Running head:
Nasal cartilage grafts
Mini-abstract

Large cartilage grafts were engineered in vitro using human nasal chondrocytes loaded into non-woven meshes, implanted in nude mice and assessed histologically, biochemically and biomechanically. We demonstrated the importance of graft pre-cultivation to enhance the clinically relevant biomechanical characteristics (i.e., suture retention at implantation and tensile/bending stiffness 2 weeks post-implantation).
Structured abstract

Objective: To investigate if pre-cultivation of human engineered nasal cartilage grafts of clinically relevant size would increase the suture retention strength at implantation and the tensile and bending stiffness 2 weeks after implantation.

Summary Background Information: In order to be used for reconstruction of nasal cartilage defects, engineered grafts need to be reliably sutured at implantation and resist to bending/tension forces about 2 weeks after surgery, when fixation is typically removed.

Methods: Nasal septum chondrocytes from 4 donors were expanded for 2 passages and statically loaded on 15x5x2mm size non-woven meshes of esterified hyaluronan (Hyaff®-11). Constructs were implanted for 2 weeks in nude mice between muscle fascia and subcutaneous tissue either directly after cell seeding, or after 2 or 4 weeks pre-culture in chondrogenic medium. Engineered tissues and native nasal cartilage were assessed histologically, biochemically and biomechanically.

Results: Engineered constructs reproducibly developed with culture time into cartilaginous tissues with increasing content of glycosaminoglycans and collagen type II. Suture retention strength was significantly higher (3.6±2.2 fold) in 2-week pre-cultured constructs than in freshly seeded meshes. Following in vivo implantation, tissues further developed and maintained the original scaffold size and shape. The bending stiffness was significantly higher (1.8±0.8 fold) if constructs were pre-cultured for 2 weeks than if they were directly implanted, whereas tensile stiffness was close to native cartilage in all groups.

Conclusion: In our experimental set-up, pre-culture for 2 weeks was necessary to engineered nasal cartilage grafts with enhanced mechanical properties relevant for clinical use in facial reconstructive surgery.
Introduction

Autologous cartilage grafts are frequently utilized in reconstructive and aesthetic surgery of the nose. The main disadvantages of this approach are the limited availability of tissue, morbidity at the donor site\textsuperscript{1,2} and time consuming surgery. In fact, the external ear and nasal septum provide only limited quantities of cartilage, and harvesting larger amounts of costal cartilage may lead to acute or delayed complications such as pneumothorax or chest wall deformities \textsuperscript{3}. Tissue engineering offers the possibility of producing large quantities of cartilage of autologous origin, starting from a small tissue biopsy and thus with minimal donor site morbidity. Recent studies have shown that human nasal chondrocytes released from a tissue biopsy and de-differentiated by expansion in monolayers, have the capacity to re-differentiate and generate cartilaginous tissue structures when cultured at high density (e.g., in micromasses or pellets \textsuperscript{4,5}) or in a variety of porous scaffolds\textsuperscript{6,7}.

In order to be used in a clinical setting for nasal reconstructive surgery, engineered cartilage grafts need to have sufficient mechanical integrity (i.e., suture retention strength) at the time of implantation, to allow for reliable suturing at the recipient site, and sufficient mechanical stability (i.e., tensile and bending stiffness) when fixation is typically removed (i.e., 2 weeks after implantation), to resist contraction by scar tissue formation and by exposure to local or external forces in the recipient bed. So far, however, both native cartilage tissue and engineered cartilage grafts have been mostly characterized biomechanically in terms of compressive stiffness \textsuperscript{7-9}, which would be of limited relevance for nasal reconstruction.

Another important issue to be addressed towards the clinical use of engineered cartilage grafts is the extent of pre-cultivation of cell-scaffold constructs prior to their implantation. In this context, previous studies indicated that pre-cultivated engineered cartilage tissues not only reach a superior quality, but display a higher capacity to further develop upon implantation than scaffolds implanted directly after seeding \textsuperscript{10,11}, possibly due to less fibrous tissue and blood vessel ingrowth. However, an independent study reported that in vitro culture time had only a minor influence on construct development \textsuperscript{7}: the issue is thus still controversial and is likely related to the scaffold used and the specific pre-cultivation conditions.

Based on the above design considerations, the aim of this study was to investigate if pre-cultivation of human tissue engineered nasal cartilage grafts of clinically relevant size would increase the suture retention strength before implantation and the tensile and bending stiffness at 2 weeks post-
implantation. In order to address this question, the selected model system consisted of human nasal chondrocytes, de- and re-differentiated using previously identified culture medium supplements \(^4,\)\(^10\), and loaded into non-woven meshes made of esterified hyaluronic acid (Hyaff\(^\circledR\)-11, Fidia Advanced Biopolymers, Abano Terme, IT), already in clinical use for the repair of articular cartilage\(^12\). The in vivo model consisted of ectopic implantation in nude mice, in a pocket between excised muscle fascia and subcutaneous tissue, resembling the environment where nasal cartilage grafts would be clinically implanted (i.e., highly vascularized mucosal tissue on one side, and thin layer of subcutaneous tissue on the other side).

**Materials and Methods**

**Cartilage biopsies**

Human nasal septal cartilage biopsies from 4 patients (mean age 48.8, range 34-61 years) were harvested at the Institute of Pathology and Forensic Medicine in Basel, following protocol approval by the local ethical committee (Ref.-No.: EK 40/03 and EK 263/03). Tissue harvesting was performed prior to the autopsy (within 36 hours post-mortem) under sterile conditions, with meticulous care to minimize mechanical trauma to the specimens. The incisions were made according to standard principles of plastic surgery in order to avoid disfigurement. A sample of about 1.5 x 2 cm of cartilage was removed by an interseptocolumellar approach and careful separation from mucosa and perichondrium. The specimen was divided into two pieces: one part for cell isolation and tissue engineering, and the other for histological, biochemical and biomechanical characterization, as detailed below.

**Chondrocyte isolation and expansion**

Chondrocytes were isolated by 22-hour incubation at 37°C in 0.15% type II collagenase and resuspended in Dulbecco’s modified Eagle’s medium (DMEM) containing 10% fetal bovine serum, 4.5 mg/mL D-glucose, 0.1mM nonessential amino acids, 1 mM sodium pyruvate, 100 mM HEPES buffer, 100 U/mL penicillin, 100 µg/mL streptomycin and 0.29 mg/mL L-glutamine (complete medium). Chondrocytes were plated in plastic dishes at a density of \(10^4\) cells/cm\(^2\) in complete medium further supplemented with 1 ng/mL Transforming growth factor-β1 (TGF-β1), 5 ng/mL Fibroblast growth factor-2 (FGF-2) and 10 ng/mL Platelet-derived growth factor-bb (PDGF-bb) (all from R&D Systems,
Minneapolis, MN). This specific combination of growth factors was previously shown to enhance human nasal chondrocyte proliferation and post expansion differentiation ability. When sub-confluent, cells were detached by sequential treatment with 0.3% type II collagenase and 0.05% trypsin/0.53 mM EDTA, and replated at 5 x 10^3 cells/cm^2. Before reaching again confluence, cells were detached and seeded on scaffolds as described below.

**Chondrocyte seeding and culture on three-dimensional scaffolds**

Cells were statically seeded at a density of 6.7E+07 cells/cm^3 on non-woven meshes (15mm width x 5mm length x 2mm thickness fleeces) made of esterified hyaluronic acid (Hyaff®-11, Fidia Advanced Biopolymers, Abano Terme, IT). Scaffolds were placed on dishes coated with a thin film of 1% agarose to prevent cell attachment to the dish bottom, and a cell suspension (1E+07cells in 60 µl) was distributed on the top surface. Constructs were statically cultured for 2 or 4 weeks in complete medium supplemented with 10 µg/mL insulin, 0.1 mM ascorbic acid and 10 ng/mL TGF-β3, with culture medium completely replaced twice a week. These supplements were previously shown to enhance chondrogenesis of de-differentiated human chondrocytes during culture into Hyaff-11 non-woven meshes. Constructs (N = 3 per condition for each donor), immediately after cell seeding or following pre-culture, were either processed for histological, biochemical and biomechanical characterization or implanted in nude mice, as described below.

**Construct implantation**

Freshly seeded scaffolds, constructs pre-cultured for 2 weeks, for 4 weeks and cell-free scaffolds as control were implanted in the back of nude mice (CD-1 nu/nu, athymic, 6 to 8-week-old females) in a pocket between excised muscle fascia and subcutaneous tissue. All animals in this study were cared for and treated according to institutional guidelines. Each mouse received two grafts, and grafts from the same experimental group were implanted in different mice. Constructs were harvested after 2 weeks, corresponding - in the clinical setting – to the time when fixation is typically removed and thus when the constructs shall have reached adequate biomechanical properties.
Histological analysis

Tissue constructs were fixed in 4% formalin for 24 h at 4°C, dehydrated, embedded in paraffin, and cross-sectioned (7 µm thick). Sections were stained with Safranin-O for sulfated glycosaminoglycans (GAG).

Biochemical analysis

Native cartilage samples and tissue constructs were weighed and digested with proteinase K (1 mg/ml protease K in 50 mM Tris with 1 mM EDTA, 1 mM iodoacetamide, and 10 µg/mL pepstatin-A) for 15 h at 56°C. GAG contents were measured spectrophotometrically using dimethylmethylene blue dye, with chondroitin sulfate as a standard. The GAG content was expressed as percentage of tissue wet weight. Total collagen and type II collagen contents were determined respectively by measurement of hydroxyproline and by inhibition enzyme-linked immunosorbent assay (ELISA), as previously described.

Biomechanical testing

Specimens were maintained in phosphate buffered solution prior to all mechanical tests and kept moist during the tests. The width and thickness of the specimens were measured with a Vernier caliper. All tests were performed by applying deflections and measuring the corresponding forces using a standard miniature mechanical testing instrument (MTS Synergie 100, MTS Systems Corporation, Eden Prairie, MN, USA), with data transmitted to a standard personal computer for subsequent calculations. Tests were conducted at room temperature.

Three point bending test

This test produces data showing the relationship between force and deflection (bending) of the specimen in the direction of the force, from which it is possible to obtain the bending stiffness of the material, a key property for materials required to maintain the shape of a structure such as the nasal septum. Generally, point loading occurs only if specimens have a cylindrical cross-section, whereas for rectangular cross-section specimens, like those used in these studies, line loading is performed (Fig. 1A). The approximate bending stiffness or modulus $E_B$ of the specimen at the deflection rate of 20 mm/minute was calculated based on the assumption that the specimen is homogenous, using the formula:
where $F$ is the applied force, $fm$ is the bending deflection in the direction of the force, and $I$ is the second moment of area, which measures the efficiency of a specific shape in resisting bending in the direction of loading. For a rectangular section of width $b$ and height $d$, the second moment of area is:

$$I = \frac{bd^3}{12}$$

For this study the support span was 10.2 mm and 1 mm was chosen as the maximal deflection. Only data from deflections in the range between 0.4 mm and 0.9 mm, where the measured forces increased almost linearly with increasing displacement, were used to calculate the slope of the load/deflection regression line. Each specimen was deflected 11 times, turned over and deflected 11 times again. Data from the first bending cycle and those during unloading were excluded. For each specimen, the bending stiffness was calculated as the mean of average values obtained in both orientations (before and after turn-over).

**Tensile test**

This test determines the elastic modulus in tension, $E_T$, of the specimen as the ratio of tensile stress to strain in the elastic region, as follows:

$$E_T = \frac{(F/A)}{(\Delta l/l_0)}$$

where $A$ is the specimen cross-sectional area at the original length $l_0$ and $\Delta l$ is the change in length between the zero force and the maximum recorded force, $F$. The specimens were secured at their lower end with a suture of a type that would be used clinically to secure a construct to the surrounding tissue (POLYSORB™ 5-0, coated, braided lactomer 9-1, synthetic absorbable suture with a P-13 needle, Syneture™). The suture was inserted 1 to 2 mm above the lower end of the specimen (Fig.1B) and fixed with a flying triple knot to the holding hook affixed to the base plate of the mechanical test machine. The knot from the suture was additionally held by a needle holder to reduce the internal sliding from the knot. The upper end of the specimen was gripped with an Allis tissue forceps (15 cm, 4 x 5 teeth), hung from a rigid metal hook attached to the load cell of the test instrument. On each specimen different points were marked with a pen to identify a fixed initial specimen "gauge" length, whose changes were analysed from video-sequences recorded during the force/elongation tests. The gauge length was between 5 and 10 mm in all cases. The video images were calibrated by recording a plastic scale placed at the same distance relative to the camera as the
sample. Each specimen was first elongated 3 times to create a maximum length change of 1.2 mm, returning the actuator to the original position after each elongation. Subsequent additional sets of 3 elongations were performed with maximal length changes of 1.8, 2.4 and 3 mm, unless the resultant force produced specimen failure (i.e., the suture tearing the tissue). The rate of elongation was set at 24 mm/minute. The calculated value of $E_T$ is approximate for several reasons, including (i) the assumption that the specimen is homogeneous in composition and structure, (ii) the use of an arbitrary rate of strain, (iii) the use of the initial rather than instantaneous area of the cross-section in the computation, and (iv) the assumption of linear force/displacement behavior over the data range used in the computations. Thus, the test was not performed to obtain precise material property data, but rather to derive relative comparisons on the tensile performance of specimens in a test resembling some aspects of in vivo loading.

**Suture pull out test**

The suture pull out test was performed to measure the maximal force that could be applied on a suture in the axial direction before pulling out from the construct. The setup was the same as in the tension test described above: at the end of the tension test, the actuator was programmed to continue elongation at a rate of 24 mm/minute until the suture pulled out of the specimen. The maximal applied force was normalized to the specimen thickness, measured prior to performing the tests, and is reported as N/mm.

**Statistical analysis**

Data are presented as mean ± standard deviation of results obtained from at least 3 constructs generated for each of the 4 donors. Mean values were compared using Mann-Whitney tests. Statistical analyses were performed using the Sigma Stat software (SPSS Inc., Version 13), with p<0.05 as the criteria for statistical significance.

**Results**

**Engineered tissues following in vitro culture**

Nasal chondrocytes from all donors could be reproducibly expanded in monolayers and underwent an average of 9.6 doublings in 14 days. After cell loading into the scaffolds, the resulting constructs
maintained the original size and shape, and already after 2 weeks of culture acquired a typical cartilaginous glossy appearance, with a firmer consistency than the original fleece (Fig. 2).

Histological cross-sections of the generated constructs indicated progressive temporal development of cartilaginous tissues (Fig. 3A-C). Freshly seeded scaffolds consisted only of a network of fibroblastic cells among Hyaff®-11 fibers (Fig. 3A). Extracellular matrix was abundant after 2 and 4 weeks of culture, with an increasing intensity of Safranin-O staining for GAG with time (Fig. 3B, C). Cells in pre-cultured constructs appeared chondrocytic, with a round morphology and embedded in large lacunae.

Biochemical analysis (Fig. 4A-C) of the pre-cultured constructs was consistent with their histological appearance. Wet weight fractions of GAG, total collagen and type II collagen were negligible in freshly seeded scaffolds and significantly increased following pre-culture, reaching levels respectively 5.5-, 8.1- and 19.5-fold lower than in the native cartilage specimens (respectively 3.3 ± 1.4, 7.8 ± 2.1 and 7.4 ± 2.0).

The suture pull out force normalized to the specimen's thickness (Fig. 4D) was 3.6-fold higher in 2 week pre-cultured constructs than in freshly seeded scaffolds, did not further increase with longer pre-culture time and reached levels 4.3-fold lower than those measured in native nasal cartilage (4.5 ± 1.9 N/mm). The suture pull out strength of the cell-free scaffolds was below the sensitivity of the test.

Engineered tissues following in vivo implantation

After 2 weeks' implantation, all constructs maintained the original size and shape of the graft and displayed a smooth, shiny surface. Tissues generated by freshly seeded scaffolds were weakly stained for Safranin-O (Fig 3D). Constructs pre-cultured for 2 or 4 weeks yielded tissues with stronger staining intensity for GAG, but predominantly in the inner region (Fig. 3E, F), where cells had a more chondrocytic morphology and were at lower density. No vascularization or mineralization was observed in any of the explants. Constructs derived by implantation of cell-free scaffolds had a very soft consistency and displayed histologically a large amount of vascular ingrowth, without any sign of cartilaginous matrix (data not shown).

The wet weight fractions of GAG and total collagen (Fig. 5A, B) were similar in explants that were grafted immediately after cell seeding or following 2 weeks of pre-culture, and significantly
higher if grafts were pre-cultured for 4 weeks, reaching levels respectively 4.5- and 4.0-fold lower than in native nasal cartilage. The wet weight fractions of collagen type II following in vivo implantation (Fig. 5C) were significantly higher if constructs were pre-cultured for 2 or 4 weeks prior to implantation than if constructs were implanted directly after seeding, and reached levels 13.1-fold lower than in native cartilage.

The modulus of elasticity in tension following 2 weeks of in vivo implantation (Fig. 5D) was not significantly different if constructs were grafted immediately after cell seeding or following 2 or 4 weeks of pre-culture. The level reached was 2.7-fold lower than in native nasal cartilage (6.4 ± 2.4N/mm²). Instead, the modulus of elasticity in bending following 2 weeks of in vivo implantation was significantly higher (rsp. 1.8/2.3 - fold) if constructs were grafted after 2 or 4 weeks of pre-culture than immediately after cell seeding (Fig. 5E). The level reached was 7.4-fold lower than in native nasal cartilage (6.8 ± 3.8N/mm²). The mechanical properties of the implanted cell-free scaffolds were below the detection level of the biomechanical test setup.

**Discussion**

With the ultimate goal of the clinical use of engineered cartilage for nasal reconstruction, in this study we demonstrated that pre-cultivation of human nasal chondrocytes into Hyaff®-11 non-woven meshes for 2 weeks yields engineered grafts with (i) significantly higher suture retention strength, a pre-requisite for reliable implantation, and (ii) significantly higher bending stiffness after 2 weeks’ implantation, a pre-requisite for safe removal of external fixation. Moreover, pre-cultivated engineered tissues were reproducibly approaching histological and biochemical properties of native nasal cartilage, which would be required to prevent fibrous tissue and vascular ingrowth and thus to support long-term stability of the graft.

Human nasal chondrocytes have been previously reported to have the capacity to generate hyaline-like cartilaginous tissues after monolayer expansion, to a higher extent than articular and rib chondrocytes. In addition, unlike articular chondrocytes, the age of the donor and quality of the donor tissue did not effect the cell chondrogenic capacity following monolayer expansion, indicating that tissue engineering of human septal cartilage is likely possible over a wide age range. Our results further emphasize the reproducibility of engineering cartilage tissues starting from human nasal chondrocytes.
Despite previous extensive characterization of human engineered nasal cartilage, to the best of our knowledge the present study is the first to use an experimental design based on clinically relevant parameters and related to issues which need to be addressed towards a clinical implementation of the procedure. In particular, the size and shape of the graft (i.e., 1.5 x 0.5 cm beam) would be compatible with the use in a variety of reconstructive surgeries of the nose, including treatment of defects at the nasal septum or alar. The extent of cell expansion (i.e., about 10 doublings), considering a previously determined yield of about 3.5E3 cells/mg of nasal cartilage tissue, would be in the range of that required to have a sufficient number of cells starting from a biopsy of a few milligrams. Unlike subcutaneous implantation used by previous studies, the in vivo model was selected to more closely resemble the environment of nasal cartilage, namely a pocket between muscle fascia and subcutaneous tissue, and in vivo implantation was for a shorter period (2 weeks), which is clinically critical as the typical time before external fixation is removed. Most importantly, the biomechanical properties assessed were those specifically required for a graft to resist contraction by scar tissue formation and by exposure to local or external forces in the recipient bed, as opposed to previously characterized properties in compression or indentation tests.

Rotter et al. observed only minor differences in the in vivo formation of engineered nasal cartilage when PLA/PGA scaffolds were implanted immediately after seeding or following pre-culture for 3 weeks. The discrepancy in comparison to our results could be explained by a number of different factors including the scaffold used, specific growth factors inducing chondrocyte redifferentiation, the time point of explantation and the different mechanical properties assessed. In this regard, however, it should be pointed out that the experimental design of our study did not include different times of implantation, and thus does not allow to derive a conclusion on whether in vitro pre-culture effectively enhances cartilage tissue development in vivo or simply anticipates the time to reach a defined level of quality.

The scaffold used for this study is a non-woven mesh composed of a benzylic ester of hyaluronic acid, a molecule naturally present in all soft tissues and playing an essential role in the maintenance of the normal extracellular matrix structure. The resulting material, commercially known as Hyaff®-11 and available in different forms (e.g., sponges, meshes), has been extensively used for studies on cartilage tissue engineering and is already in clinical use for the repair of articular cartilage defects. The result that a pre-culture of 2 weeks improved the suture retention...
strength of engineered grafts is clearly related to the fact that the mesh used has intrinsically negligible mechanical properties. This observation allows to conclude that the mechanical properties reached by the grafts were merely due to the deposition and/or functional organization of new extracellular matrix, and therefore are not likely to reduce with time due to scaffold degradation. Interestingly, the modulus of elasticity in tension was not modulated by pre-cultivation time, and reached levels closest to native tissue as compared to all other parameters, suggesting that tensile properties of engineered cartilage are not a critical read-out in quality assessment. A longer implantation time was not the objective of the present study, although previous works 7,9 reported that engineered nasal cartilage tissues improved biochemical and biomechanical similarity to native tissue with time of implantation. The lack of a direct correlation between the collagen and GAG content and the measured mechanical properties of the tissues suggests the importance of a functional organization of those molecules and prompts for future investigations on the assessment of the level of collagen crosslinking.

In conclusion, the results of the present study demonstrate the possibility to develop in vitro a nasal cartilage graft with clinically relevant size and biomechanical properties. Furthermore, our data indicate a possible advantage in the pre-culturing of engineered human nasal cartilage grafts for 2 weeks prior to implantation, and together with other promising reports on the topic prompt for the clinical test of pre-cultivated grafts in nasal reconstructive surgery.

Acknowledgments

The authors would like to acknowledge Fidia Advanced Biopolymers (Abano Terme, IT) for the generous supply of Hyaff®-11 meshes, and thank Andrea Barbero, for his scientific and technical assistance.
