We report the characterization of Cep170, a forhead-associated (FHA) domain protein of previously unknown function. Cep170 was identified in a yeast two-hybrid screen for interactors of Polo-like kinase 1 (Plk1). In human cells, Cep170 is constantly expressed throughout the cell cycle but phosphorylated during mitosis. It interacts with Plk1 in vivo and can be phosphorylated by Plk1 in vitro, suggesting that it is a physiological substrate of this kinase. Both overexpression and small interfering RNA (siRNA)-mediated depletion studies suggest a role for Cep170 in microtubule organization and cell morphology. Cep170 associates with centrosomes during interphase and with spindle microtubules during mitosis. As shown by immunoelectron microscopy, Cep170 associates with subdistal appendages, typical of the mature mother centriole. Thus, anti-Cep170 antibodies stain only one centriole during G1, S, and early G2, but two centrioles during late G2 phase of the cell cycle. We show that Cep170 labeling can be used to discriminate bona fide centriole overduplication from centriole amplification that results from aborted cell division.

INTRODUCTION

The centrosome is the major microtubule (MT) organizing center of animal cells and exerts a profound influence on most MT-related cellular functions, including cell motility and polarity, the transport of organelles, and cell division (Nigg, 2004). It comprises a pair of barrel-shaped centrioles that are surrounded by pericentriolar material (PCM). The structure of centrioles in cultured mammalian cells has been analyzed in detail by electron microscopy (EM), and characteristic cell cycle-related changes are well described (Rieder and Borisy, 1982; Chretien et al., 1997). The proximal and distal ends of centrioles, as well as their degree of maturation, can be distinguished by the presence or absence of specific structures: only the older of the two centrioles (often referred to as the mother centriole) carries appendages at its distal end, and so these structures serve as markers for the age of centrioles. A second type of appendages, termed subdistal, also has been described. These are generally thought to be acquired during G1 by the older centriole but then disappear again at the onset of mitosis (Chretien et al., 1997; Bornens, 2002; Meraldi and Nigg, 2002). MTs are nucleated from the centriole-associated PCM regardless of the presence or absence of appendages, but they are preferentially anchored at the distal end of the mother centriole (Piel et al., 2000). Several proteins specifically associated with mother centrioles have recently been described. These include ODF2/cenexin (Lange and Gull, 1995; Nakagawa et al., 2001), e-tubulin (Chang et al., 2003), ninein (Piel et al., 2000), ninein-like protein (Nlp; Casenghi et al., 2003), adenosomatous polyposis coli and EB1 (Louie et al., 2004), and centrinulin (Gromley et al., 2003). Ninein is thought to form part of a MT-anchoring complex (reviewed in Bornens, 2002; Mogensen, 2004) and important roles in MT organization have also been attributed to Nlp and EB1 (Casenghi et al., 2003; Louie et al., 2004). e-Tubulin has been reported to be required for centrosome duplication in frog egg extracts (Chang et al., 2003), and centrinulin has been implicated in cytokinesis (Gromley et al., 2003).

The precise function of centrioles remains mysterious, but several intriguing roles have been proposed. Injection of antibodies directed against posttranslationally modified centriolar tubulin induced not only a transient disassembly of centrioles, but also the dispersal of the PCM, indicating that centrioles are critical for centrosome stability (Bobinnec et al., 1998). Moreover, a specific movement of the mother centriole to the midbody has been linked to the terminal separation of dividing cells (abscission), indicating that centrioles contribute to the control of cytokinesis (Piel et al.,...
2001). The mechanical removal or laser-mediated ablation of centrioles, though not preventing entry into mitosis, caused frequent cytokinesis failure and cell cycle arrest in the subsequent G1 phase (Hinchcliffe et al., 2001; Khodjakov and Rieder, 2004).

Structure and activity of the centrosome are regulated throughout the cell cycle (Fry and Hames, 2004). One important change occurs at the onset of mitosis, when the centrosome undergoes a process called maturation. This is reflected by both the acquisition and loss of specific centrosome components and results in increased MT nucleation capacity. Concomitantly, subdistal appendages are lost from centrioles, leading to a more diffuse anchoring of MTs at spindle poles (Chretien et al., 1997; Bornens, 2002). Prominent among the enzymes implicated in the regulation of centrosome maturation is Polo-like kinase 1 (Plk1) (Sunkel and Glover, 1988; Lane and Nigg, 1996; Barr et al., 2004). Candidate centrosomal substrates of this kinase have recently been identified (do Carmo Avides et al., 2001; Casenghi et al., 2003), but a complete understanding of the role of Plk1 at the centrosome remains elusive.

In the present study, we have produced a yeast two-hybrid screen to search for novel interaction partners of Plk1. We report the characterization of a human protein of ~170 kDa that contains a forkhead-associated (FHA) domain in its N terminus. We have localized this protein to the centrosome and hence refer to it as Cep170 (for centrosomal). Our data indicate that Cep170 is involved in the control of cell morphology and interacts with Plk1 under physiological conditions. Finally, we show that Cep170 constitutes an excellent marker for centriole maturation during the cell cycle and that the acquisition of Cep170 can be used to distinguish distinct mechanisms leading to centrosome amplification.

**Materials and Methods**

**Antibody Production**

Polyclonal rabbit antibodies were raised against N- (aa 15–754) and C-termini (aa 755–1460) fragments of KIAA0470/Cep170, both His-tagged at their N-termini and expressed in *Escherichia coli*. Two rabbits were immunized for each antigen (BioGenes, Berlin, Germany). Antibodies against the N-terminal half of Cep170 were affinity purified on recombinant immunogen bound to an AffiGel 15 (Bio-Rad, Hercules, CA) column and used throughout this study. Importantly, both antibodies produced qualitatively similar results.

**Cell Culture, Synchronization, and Transfections**

All cells were grown at 37°C in a 5% CO2 atmosphere in DMEM, supplemented with 10% fetal calf serum (FCS) and penicillin-streptomycin (100 IU/mL and 100 µg/mL, respectively). U2OS cells stably expressing centrin-GFP (GFPI) kindly provided by M. Bornens, Institut Curie, Paris, France) were maintained as described previously (Duensing et al., 2001). For synchronization, HeLa cells were treated with 2 µM thymidine and then released in medium for 14 h, arrested again by 14 h of aphidicolin treatment (1.6 µg/mL) and harvested at different times after release into fresh medium. For M phase arrest, cells were treated with 0.5 µg/mL nocodazole for 16 h. Alternatively, 0.1 µg/mL nocodazole was added 8 h after release from a G1/S arrest, and cells were collected by shake-off 6 h later. For in vivo labeling experiments, cells were synchronized and labeled as described previously (Mayor et al., 2002). NIH/3T3 were serum starved by culturing in DMEM supplemented with 0.5% FCS for 48 h. U2OS/centrin-GFP cells were treated with either 0.6 µg/mL cytochalasin D for 48 h to block cytokinesis or with 1 mM hydroxyurea (HU) for 72 h to induce centrosome overduplication. U2OS cells were transfected using the calcium phosphate precipitation method as described previously (Seelos, 1997). When transfection was combined with RNA interference (RNAi), cells were transfected with the small interfering RNA (siRNA) oligos as described below ("siRNA experiments"); after 60 h cells were transfected with the DNA plasmid and, 12 h later, fixed and processed for immunofluorescence (IF) microscopy. U2OS/centrin-GFP cells were transfected with 2 µg of plasmid DNA encoding human papilloma virus type 16 (HPV-16) E7 or empty pCMVneo vector (Duensing et al., 2003) by using FuGENE 6 (Roche Diagnostics, Mannheim, Germany). Cells were cotransfected with 0.2 µg of vector encoding cyan fluorescent protein (CFP) with a mitochondrial target sequence (BD Biosciences Gentech, Palo Alto, CA). Cells were processed for IF microscopy at 48 h posttransfection.

**Plasmid Preparation**

The KIAA0470 cDNA was obtained from the Kazusa DNA Research Institute. It was subcloned into pT7-EGFP-C1 or pT7-EGFP-N1 (modified from pEGFP-C1 or pEGFP-C1-1, BD Biosciences Clontech), after removing the ATG or the stop codon using KIAA0470 deletion clones produced in pT7-EGFP-C1: N-term (aa 2–754, until XmnI site in the cDNA), C-term (aa 755–1460, from XmnI site to the end of cDNA), C-termII (aa 1015–1460, from HindIII in the C-term to the end of cDNA), and ΔFHA (aa 74–1460, from Accl site to the end of cDNA). Following KIAA0470-encoded proteins were produced in pQE bacterial expression vectors (QIAGEN, Hilden, Germany); full length (pQE32), N-term (aa 15–754, BssSI-XmnI fragment), C-term, and C-termII (pQE30) as described above for the enhanced green fluorescent protein (EGFP)-tagged clone.

**Immunofluorescence and Immunoprecipitation (IF) Experiments**

Cells were directly lysed in gel sample buffer, resolved by SDS-PAGE, and electrophoretically transferred to nitrocellulose membranes (Schleicher &

Molecular Biology of the Cell
Catalytically inactive His6-Plk1 purified from baculovirus-infected Sf9 insect cells (Casenghi et al., 2002), by using equal amounts of recombinant proteins with wild-type or inactive Plx1N172A (Plk1 of Rattus norvegicus; Moudjou and Bornens, 1994). Yeast two hybrid screens have been described previously (Casenghi et al., 2002). To identify proteins interacting with Polo-like kinases, a protein purificado Cep170 and deletion mutants were expressed and purified from E. coli as described above. In vitro kinase assays were performed as described previously (Descombes and Nigg, 1998; Kelm et al., 2002), by using equal amounts of recombinant proteins with wild-type or catalytically inactive His6-Plk1 purified from baculovirus-infected Sf9 insect cells. Casein was used as control. Incubation was performed for 30 min at 30°C and then reactions were stopped by adding 5× gel sample buffer. After electrophoresis, phosphate incorporation was determined by autoradiography.

Purification of Recombinant Proteins
His6-tagged Cep170 and deletion mutants were expressed in E. coli (MI109 or JM109pRIL strains and purified under native conditions by using standard protocols (QiAexpressionist system; QiAGEN). After purification, buffer was exchanged to PBS + 1 mM PMFS, or PBS only for rabbit injections.

siRNA Experiments
The siRNA sequence targeting Cep170 corresponds to the coding region 2237–2255 (relative to the KIAA0470 cDNA sequence): GAA GGA AUC CUC UAA GGA AUC CAA GUC A. For control, a duplex (GL-2) targeting luciferase was used (Elbashir et al., 2001). The 21-nt RNA duplexes were purchased from Dharmacon Research. Annealing of the siRNAs and transfections using Oligo-fectamine (Invitrogen, Carlsbad, CA) were performed as described previously (Elbashir et al., 2001).

Miscellaneous
The isolation of human centrosomes from KE37 cells was performed by spinning the cell lysates at 50,000 × g for 45 min in a sucrose gradient of 40%, 50%, and 70%, as described in Moudjou and Bornens, 1994. Yeast two hybrid screens have been described previously (Casenghi et al., 2003).

RESULTS
Identification of Cep170 (KIAA0470) as a Centrosomal Protein
To identify proteins interacting with Polo-like kinases, a yeast two-hybrid screen was performed with catalytically inactive Plx1N172A (Plk1 of Xenopus laevis) as bait. One cDNA isolated in this screen, PXP-6, showed homology to a human database entry (KIAA0470, also termed KAB [for KARP-1 binding protein], predicted to give rise to three splice variants). These cDNAs (accession nos. AB022657, AB022658, and AB022659) are predicted to code for proteins with molecular weights of ~170 kDa, which display a region of 64–68% identity to the PXP-6–predicted protein product (depicted schematically in Figure 1A). By reverse transcription-polymerase chain reaction, all three splice forms are expressed in U2OS and HeLa cells (our unpublished data). All three proteins harbor a putative FHA-domain in the N terminus (aa 22–73, by using the numbering of splice form 1), as well as a serine-rich region (aa 968–1228) and a small predicted coiled-coil region (aa 1467–1495) in the C-terminus (Figure 1A).

When tagged with GFP, both the product of the partial PXP-6 cDNA and a full-length human KIAA0470 protein co-localized with Plx1/Plk1 at the centrosome (our unpublished data; but see Figure 4). This co-localization prompted us to further characterize this human protein and to investigate its possible interaction with Plk1. Polyclonal rabbit antibodies were raised against nonoverlapping N- and C-terminal halves of the human KIAA0470 protein expressed in E. coli. Both antibodies were expected to recognize all three splice products. By Western blotting on a total HeLa cell extract, the anti-N-terminal antibody reacted with a band of the size expected for KIAA0470 protein (Figure 1B), and this immunoreactivity was readily competed by preincubation with recombinant N-terminal but not C-terminal fragment of the antigen (compare lanes 2 and 3). A band of identical migration also was seen in U2OS and KE37 cell extracts and in purified centrosomes (Figure 1B). Moreover, in a sucrose gradient preparation of centrosomes, the KIAA0470 protein co-fractionated with the γ-tubulin centrosomal marker (Figure 1C). Together with the immunolabeling data shown below, these results confirm the prediction of a recent proteomic survey of the human centrosome (Andersen et al., 2003) and identify KIAA0470 as a novel centrosome component. In line with the convention proposed by Andersen et al. (2003), we will henceforth refer to this protein as Cep170 (centrosomal protein of approximately 170 kDa) and to the three splice forms as Cep170 α, β, and γ, respectively (Figure 1A).

The localization of endogenous Cep170 in human cells was determined by IF analysis. In most cells, staining of a small, often circular or horseshoe-shaped structure was observed (Figure 1D, a). This staining was not seen with pre-immune serum (our unpublished data) and was effectively competed by incubation with antigen (Figure 1D, b). As expected, the structures stained by anti-Cep170 antibodies co-localized with γ-tubulin (Figure 1D, c). The centrosome association of Cep170 was not abolished by nocodazole-induced depolymerization of MTs (our unpublished data), and isolated centrosomes also stained strongly positive (Figure 1D, d). In many cases, Cep170 associated preferentially with one of two centrioles (Figure 1D, c and d), a finding to which we will return in more detail below. With the onset of mitosis, staining of the centrosome became progressively more diffuse, so that by metaphase, Cep170 was associated with spindle MTs in the region of the poles, but staining of the poles themselves was not pronounced (Figure 2, a and a’ and b and b’). The MT-associated staining persisted during anaphase (Figure 2, c and c’). In early telophase, strong staining of astral MTs could be seen (Figure 2, d and d’), and
in late telophase Cep170 reassociated with the centrosomes (Figure 2, e and e'). These localization data demonstrate that Cep170 displays a dynamic association with elements of the MT cytoskeleton throughout the cell cycle.

Cep170 Is Phosphorylated during M Phase and Interacts with Plk1
Western blots using extracts from G1/S or M phase-arrested HeLa cells revealed little difference in abundance of Cep170 during the cell cycle but a striking change in mobility, suggesting a mitosis-specific posttranslational modification (Figure 3A, left). IP experiments performed on 32P-labeled cells confirmed that Cep170 is a phosphoprotein, with a phosphorylation peak in G2/M (Figure 3A, top). As shown by Western blotting, comparable amounts of Cep170 were immunoprecipitated from all cell cycle stages (Figure 3A, bottom), and no significant signals were observed in control IP (Figure 3A). Considering that the phosphorylation peak of Cep170 coincides with the time of maximal Plk1 activity in the cell cycle (Golsteyn et al., 1995) and that Cep170 was isolated in a yeast two-hybrid screen with Plk1 as bait, we asked whether these two proteins could interact in human

Figure 1. Cep170 localizes to centrosomes. (A) Schematic representation of the predicted protein products of a X. laevis cDNA isolated in the yeast two-hybrid screen (PXP-6) and of three homologous human cDNA splice variants. The black and gray boxes indicate the FHA and the serine-rich domains, respectively. Dotted lines indicate gaps and the open triangle an insertion, presumably resulting from differential splicing. Vertical dashed lines delineate the region of homology between the X. laevis and human proteins, as calculated using the FASTA protein program. We believe that the start codon for the corresponding cDNAs is the ATG positioned at nucleotide 54 in the KIAA0470 clone (accession no. AB007939), because of 1) the presence of stop codons in the 5' untranslated region, 2) the presence of an A at -3 respect to the ATG (consensus Kozak sequence), and 3) sequence conservation with a mouse cDNA sequence (accession no. BC050077). (B) Western blot using the Cep170 antibody on total extracts from HeLa (lanes 1–3), U2OS (lane 4), or KE37 (lane 5) cells or the isolated centrosomal fraction from KE37 cells (csome, lane 6). Primary antibody was preincubated with buffer (lane 1), the immunogen (+ N-term, lane 2) or a nonoverlapping fragment of Cep170 (+ C-term, lane 3). Molecular weight markers are indicated on the left. Vertical lines delineate separate nitrocellulose stripes. (C) Western blot using Cep170 and γ-tubulin antibodies on fractions (5–11) from a discontinuous sucrose gradient (see Materials and Methods) harboring partially purified centrosomes. Total KE37 extract (TOT) was loaded as control. (D) IF staining of HeLa cells (a–c), or isolated centrosomes (d). Cells were stained with Cep170 antibody (a and b; the arrowhead indicates the centrosomal staining) after preincubation with buffer (a) or the immunogen (b), or double stained (c and d) with anti-Cep170 (red) and anti-γ-tubulin (c) or GT335 (d) (green) antibodies. Bars, 10 μm (a–c), 5 μm (d).
overexpression affects centrosome positioning through a disturbance of MT dynamics.

RNAi-mediated Cep170 Depletion Perturbs Cytoskeletal Organization and Cell Shape

To explore the function of Cep170 in human cells, siRNA experiments were carried out. Transfection of both HeLa and U2OS cells with a siRNA duplex oligonucleotide spe-
specific for Cep170 resulted in substantial depletion of Cep170 after 60 h, as shown by both IF microscopy (Figure 5, A and B) and Western blotting (Figure 5C), whereas no depletion was seen in response to a GL2 control oligonucleotide. Cep170 depletion did not significantly affect the centrosomal recruitment of any protein tested (β-1-tubulin, centrin-2, polyglutamylated tubulin [GT335], C-Nap1, Nek2, Plk1, and Aurora-A). Instead, striking changes were apparent in MT organization and in the shape of interphase cells. Whereas the shape of HeLa cells changed from a typical epithelial (cobblestone) to a more fibroblastic (elongated) appearance (Figure 5A), U2OS cells depleted of Cep170 showed an apparent increase in size, affecting both the nucleus and the cytoplasm (Figure 5B). It is possible that Cep170-depleted U2OS cells were arrested or delayed during interphase, because mitotic cells were almost absent from such cultures (0.5% ± 0.1 compared with the 4.4% ± 0.6 in control cultures). However, neither FACS analysis nor centrosome counting provided evidence for an increase in ploidy (our unpublished data). Cep170-depleted HeLa cultures did not show a significant decrease in the percentage of mitotic cells (7.4% ± 1.4 compared with the 7% ± 0.6 of control cultures). We cannot presently explain why HeLa and U2OS cells displayed somewhat different responses to the depletion of Cep170, but the observed morphological changes clearly suggest a role for Cep170 in cytoskeletal organization.

**Changes in Cep170 Localization during the Cell Cycle**

The localization studies described above had suggested that endogenous Cep170 preferentially associates with only one
of two parental centrioles within the interphase centrosome (Figure 1D). This asymmetric staining was intriguing, because the two centrioles differ in both structure and function (Bornens, 2002). To determine whether the asymmetric localization of Cep170 varies during the cell cycle, HeLa cells were synchronized and costained for Cep170 and either γ-tubulin or centrin-2 (Figure 6, A and B). To obtain cultures enriched in G1, S, or G2 phases, cells were arrested at the G1/S transition by thymidine/aphidicoline treatment and then released and harvested at different time points. In parallel, the DNA content of the corresponding cell populations was determined by laser scanning cytometry (Figure 6C). In the majority of cells arrested at G1/S, Cep170 was clearly associated with only one of the two γ-tubulin-positive centrioles, and the same was true after a 4-h release from the block, when cells were passing through S phase (Figure

![Image of Figure 4 showing Cep170 localization and G1/S transition with thymidine/aphidicoline treatment.](image-url)
6, A and C). However, upon progression through G2 (9–12 h after release), an increasing number of cells showed Cep170 association with both $\alpha$-tubulin dots (Figure 6, A and C). In many of these latter cells, centrosomes were separated by $>5 \mu$m, suggesting that they were in late G2. Cells also were stained with an anti-centrin-2 antibody, to visualize single centrioles. In all cells that contained two centrioles (i.e., the G1 configuration), Cep170 associated with only one (Figure 6B, top), and even in cells in which four centrioles could clearly be discerned by centrin staining (i.e., the G2 configuration), two Cep170-positive structures were seen only in a subpopulation (our unpublished data). In contrast, in all cells in which the anti-Cep170 antibody labeled two structures, four centrin-positive centrioles could be seen (Figure 6B, bottom). Together, these data indicate that the recruitment of Cep170 to the second parental centriole begins late in G2 and probably continues into M phase (Figure 6D).

Cep170 Localizes to Centrosome Appendages
In response to serum starvation, NIH 3T3 fibroblasts grow a primary cilium specifically from the older, mature centriole (Albrecht-Buehler and Bushnell, 1980). This primary cilium can be visualized by antibodies against acetylated tubulin, affording a convenient assay for determining which of the two parental centrioles was labeled by the Cep170 antibody (Figure 7A). Whereas $\gamma$-tubulin was present on both centrioles in serum-starved NIH 3T3 cells (Figure 7A, left), Cep170 was invariably seen on the one centriole that grew the primary cilium (Figure 7A, middle and right). This unequivocally demonstrates that Cep170 localizes to the older of the two parental centrioles. As seen in human cells, Cep170 staining in these murine cells was often ring-shaped, but sometimes three dots could clearly be seen (Figure 7A). This suggested that Cep170 associated with structures that are specific to the mature cilium. To explore the localization of Cep170 at an ultrastructural level, HeLa and U2OS cells were analyzed by both preembedding immuno-EM (Figure 7B, a–d) and labeling of ultrathin cryosections (Figure 7B, e), performed on whole cells. Using the preembedding technique, anti-Cep170 antibodies produced strong labeling at the distal end of one of the two centrioles (Figure 7B, a and b, and d1–d4). In addition, a weaker staining was observed at the proximal end of both centrioles (Figure 7B, a and d1–d4). The distal staining was largely associated with the subdistal appendages, characteristic of the mother cilium (Bornens, 2002). Ultrathin cryosections of nonpermeabilized cells largely confirmed these results (Figure 7B, e). Again, subdistal appendages were clearly labeled, although staining at proximal ends was not observed. These results demonstrate that Cep170 preferentially associates with appendages that are typical of the fully mature cilium.

Use of Cep170 for Studying Centriole Amplification Mechanisms
It occurred to us that markers for mature centrioles, such as Cep170, could be used to investigate the molecular mechanisms that underlie numerical centrosome aberrations. Such
aberrations are frequently seen in tumor cells, but their molecular origins are presently unclear. As one important example of cells displaying a centrosome amplification phenotype, we examined U2OS cells in which supernumerary centrioles were induced by expression of HPV-16 oncoprotein E7 (Duensing et al., 2000; Munger et al., 2001). In parallel, we analyzed U2OS cells in which supernumerary centrosomes were deliberately induced through treatment with either HU, known to cause repeated rounds of centrosome duplication (Balczon et al., 1995; Meraldi et al., 1999), or cytochalasin D, known to cause division failure (Meraldi et al., 2002). U2OS cells stably expressing centrin-GFP (Duensing et al., 2000) were transiently transfected with HPV-16 E7 or empty vector, together with a transfection marker, and 48 h later they were stained with anti-Cep170 antibodies (Figure 8). As expected, the expression of HPV-16 E7 significantly prolonged S phase and increased the percentage of cells with abnormal numbers of centrioles (>4/cell) compared to controls (10.5 ± 1.3 and 3.1 ± 1.9%; p ≤ 0.005), consistent with previous results (Duensing et al., 2000, 2001). When analyzed for Cep170 staining, the majority of HPV-16 E7-transfected cells (68.1%) with abnormal centriole numbers contained only one Cep170-positive centriole (Figures 8B, top, and C). About 24.2% of cells showed 2 Cep170-positive centrioles, suggesting that these cells had progressed sufficiently far in the cell cycle (late G2/M) to allow maturation of the second parental centriole. A very similar result was obtained when analyzing the frequency of Cep170-positive centrioles in HU-treated U2OS cells (Figures 8B, middle, and C). These results strongly indicate that E7 causes centrosome amplification by an overduplication mechanism similar to the one operating during prolonged S phase arrest in HU-treated U2OS cells. In striking contrast, virtually all of the cytochalasin D-treated U2OS/centrin-GFP cells displayed two or more (up to 5) Cep170-positive centrioles (Figures 8B, bottom, and C). This result is in line with expectation, because supernumerary centrosomes arising through division failure are predicted to harbor mature centrioles. Together, these results illustrate that Cep170 staining can distinguish a centrosome amplification phenotype arising through deregulation of centriole duplication from the consequences of aborted divisions. From a more general perspective, they suggest that Cep170 (or other markers for mature centrioles) may constitute invaluable

Figure 6. Asymmetric Cep170 localization during the cell cycle. (A) Costaining of HeLa cells at the indicated cell cycle phases with antibodies against Cep170 (red) and γ-tubulin (green); DNA is shown in blue. Enlargements of centrosomes are shown on the right. (B) HeLa cells containing two (top) or four (bottom) centrioles, costained with antibodies against Cep170 (FLUOS-conjugated, green) and centrin-2 (red). DNA is shown in blue. Insets show single centrosomes. (C) Quantitative analysis of the experiment shown in A. The upper part of the table indicates the percentage of cells with Cep170 staining on one or two centrioles. The lower part shows the percentage of cells in G1, S, and G2/M phases, as determined by laser scanner cytometry. (D) Schematic representation of Cep170 association with centrioles during the cell cycle. Gray and empty rectangles represent parental centrioles and newly emerging (pro-) centrioles, respectively and the black ovals symbolize Cep170 localization. Bars, 10 μm.
diagnostic tools for exploring the mechanisms underlying the genesis of supernumerary centrioles both in vitro and in vivo.

DISCUSSION

We have characterized a centrosome protein, Cep170, which we isolated as a novel interaction partner of Plk1. The centrosome association of this protein confirms a recent prediction based on mass spectrometry and protein correlation profiling (Andersen et al., 2003). We show that Cep170 is expressed throughout the cell cycle. It associates with the centrosome in interphase and with the spindle apparatus during mitosis. In the G2 and M phases, Cep170 is phosphorylated extensively, and several lines of evidence point to Plk1 as a possible upstream kinase: 1) Plk1 is activated at the time in the cell cycle when Cep170 is phosphorylated in vivo; 2) Cep170 interacts with Plk1 in both a yeast two-hybrid assay and, at endogenous levels, within human cells; and 3) Cep170 is an in vitro substrate of recombinant Plk1. A detailed analysis of the function and physiological relevance of Cep170 phosphorylation will have to await the identification and subsequent mutation of physiological phosphorylation sites. However, it is intriguing that the site/s phosphorylated in vitro by Plk1, the Plk1–Cep170 interaction domain, and the centrosomal targeting domain of Cep170 all map to the C-terminal half.

Overexpression of Cep170 in U2OS cells induced strong MT bundling, suggesting that Cep170 is able to bind MTs with a high affinity. Deletion mapping studies implicated the C-terminal half of Cep170 in both MT binding and bundling and suggested the existence of more than one MT-binding domain. Although no previously described MT-binding motif could be recognized in the Cep170 sequence, the C terminus harbors a serine-rich region, a domain that is implicated in MT binding in the case of the CLIP-115 protein (Hoogenraad et al., 2000). Interestingly, cells overexpressing the C terminus of Cep170 frequently showed displacement of the centrosome from its typical perinuclear location to the cell periphery, implying a major rearrangement and polarization of the cytoskeleton. Because this phenotype resembles that caused by inhibition of dynein (Burakov et al., 2003), it is possible that Cep170 and dynein cooperate in centrosome–MT organization. In support of this possibility, preliminary results indicate that dynactin and Cep170 can interact in human cells (Guarguaglini and Nigg, unpublished data).

siRNA could be successfully used to deplete Cep170 from human cells. Depletion of Cep170 did not cause any obvious defects in centrosome structure. All centrosome proteins examined localized correctly, and microtubule nucleation was not significantly impaired (Guarguaglini and Nigg, unpublished data). Instead, drastic changes in cell shape and overall organization of the interphase cytoskeleton were observed, suggesting that Cep170 is involved in the regulation of microtubule dynamics. How Cep170 contributes to control cell shape is not yet clear, but a priori, it could act not only through the microtubule but also the actomyosin cytoskeleton. In support of the latter possibility, it is intriguing that, similar to Cep170 (see below), p160ROCK localizes to mother centrioles (Chevrier et al., 2002). This kinase coordinates actin organization with the MT network, and its inhibition was reported to cause the formation of elongated MTs, similar to the phenotype observed here upon depletion of Cep170. Moreover, inhibition of p160ROCK caused a relocalization of the mother centriole toward the cell periphery, reminiscent of the phenotype seen upon overexpression of the Cep170 C terminus. In view of these similarities, it will be interesting to investigate a possible functional link between p160ROCK and Cep170.

A striking feature of Cep170 is its asymmetric distribution within the centrosome. As demonstrated by both IF and EM microscopy, Cep170 belongs to a growing group of proteins that preferentially localize to the mother centriole, usually by virtue of an association with subdistal appendages (Lange and Gull, 1995; Fied et al., 2000; Nakagawa et al., 2001; Casenghi et al., 2003; Chang et al., 2003; Gromley et al., 2003; Louie et al., 2004). Although these proteins have been implicated in different processes, subdistal appendages seem to be important sites for MT anchoring (Bornens, 2002; Mogensen, 2004). It is plausible, therefore, that

Figure 7. Localization of Cep170 to appendages on the mature centriole. (A) Costaining of serum-starved NIH 3T3 cells with antibodies against acetylated tubulin (red) and either γ-tubulin or Cep170 (green), as indicated. Insets show enlargements of centrosomes and cilia. Bar, 10 μm. (B) Immuno-EM localization of Cep170 in U2OS cells. Preembedding (a–d): longitudinal section of one centrosome (a); transversal section of one centriole with the typical “crown” labeling produced by the anti-Cep170 antibody (b); control staining with secondary antibody only (c); and serial longitudinal sections through one centrosome (arrows indicate labeling of appendages, arrowheads mark the proximal staining at both centrioles) (d1–d4). Ultrathin cryosection (e), enlarged image of one centrosome; arrows indicate labeling of appendages. Bars, 250 nm.
several proteins work in concert to control MT anchoring to centriolar appendages, which in turn may contribute to regulate different aspects of centrosome functions during the cell cycle.

Cep170 clearly constitutes a specific marker for centriole maturation. Here, we have explored the possibility of using Cep170 for the selective identification of mature parental centrioles in cells displaying a centriole amplification phenotype. It is well established that several oncproteins, notably the human papillomavirus E7 protein, induce the appearance of supernumerary centrosomes in both cultured cells and tumors. By staining centrioles with the anti-Cep170 antibody, we were able to show that HPV16/E7-transfected cells contain a normal number of mature (Cep170-positive) centrioles (1 or 2) and an increased number of immature (Cep170-negative) ones.

Very similar results were obtained when centrosome overduplication was induced by culturing cells in HU, indicating that the overproduction of centrioles in the absence of passage through mitosis is not accompanied by the acquisition of maturation markers on newly generated centrioles. Conversely, cells in which centrioles accumulated due to failed cytokinesis generally displayed at least two, and often more than two, Cep170-positive centrioles, reflecting the fact that centrosome amplification in these cells had occurred through passage through at least one aborted mitosis, with the concomitant acquisition of Cep170 on the maturing centriole(s). These results illustrate that centriole maturity markers such as Cep170 can be used as powerful tools to discriminate between distinct mechanisms leading to centriole accumulation. In princi-
ple, such markers may prove useful to study any process in which the degree of centriole maturation can provide mechanistic information on centriole biogenesis.

The majority of known centrosomal proteins contain large coiled-coil regions. In contrast, Cep170 contains only a very short coiled coil. Instead, it harbors a putative FHA domain in its N terminus. Such domains are generally implicated in phosphopeptide recognition (Hofmann and Bucher, 1995; Li et al., 2000; Durocher and Jackson, 2002) and frequently observed in proteins that function in DNA damage response pathways. This is intriguing for two reasons: first, growing evidence links DNA damage responses to centrosomes and the G2/M transition (Sibon and Theurkauf, 2004), and second, Plk1 is inactivated after DNA damage and may interact with the FHA-containing protein Chk2, a central regulator of the DNA damage response (Smits et al., 2000; van Vuig et al., 2001; Tsvetkov et al., 2003). The identification of an FHA domain in the Plk1 interactor Cep170 strongly suggests that this protein is involved in a signaling pathway. The identification of this pathway constitutes one of the major challenges for future enquiry into the function of Cep170.
