An enantioselective artificial Suzukiase based on the biotin–streptavidin technology†

Anamitra Chatterjee, Hendrik Mallin, Juliane Klehr, Jaicy Vallapurackal, Aaron D. Finke, Laura Vera, May Marsh and Thomas R. Ward*

Introduction

The palladium-catalyzed Suzuki–Miyaura cross-coupling reaction (SMC hereafter) of organic halides with boronic acids is one of the most versatile methods for the synthesis of biaryls. Such structural motifs are present in numerous agrochemicals, natural products, pharmaceuticals, and polymers. For this purpose, the SMC has been widely studied. More recently, the SMC has found applications in the context of chemical biology. Indeed, both reactants and products can be regarded as bio-orthogonal. In this promising context however, high catalyst loadings are routinely required with reactions performed in a biological environment.

In stark contrast to the SMC, Nature relies on very different mechanisms to install (atropisomeric) Caryl bonds. Despite numerous reports on asymmetric SMC in organic media, only two reports describe enantioselective SMC in water. Uozumi reported on an heterogeneous SMC in water requiring a high catalyst loading (TON < 10, 94% ee at 80 °C). More recently, Kündig et al. reported an asymmetric SMC in an water–organic solvent mixture (TON = 17, up to 80% ee) at room temperature. To complement these efforts, we speculated that, thanks to their well-defined second coordination sphere, artificial metalloenzymes (ArMs hereafter) may offer a propitious environment to engineer an asymmetric “Suzukiase” that is, an enzyme that catalyzes the SMC. ArMs result from the incorporation of an abiotic cofactor within a macromolecule (protein or oligonucleotide). In this context, Ueno and coworkers anchored a palladium moiety within a ferritin container to yield an artificial Suzukiase. The resulting artificial Suzukiase however did not outperform the free cofactor (no enantioselectivity, turnover frequency TOF: 3500 h⁻¹, no TON mentioned). Inspired by a seminal contribution by Whitesides in 1978, we report herein our effort to engineer an asymmetric artificial Suzukiase based on the biotin–streptavidin technology.

Results and discussion

With the aim of identifying suitable cross-coupling reaction conditions, we evaluated five different biotinylated catalyst precursors 1–5 in the presence of either avidin or streptavidin (Avi and Sav hereafter). For this purpose, the reaction of 1-naphthalenecarboxylic acid 7c with 2-methoxy-1-naphthaleneboronic acid was selected as a model system (Scheme 1). Initial experiments revealed that protonolysis of the boronic acid led to modest cross-coupling yields. Systematic variation of the base, pH, and organic co-solvent led to the identification of suitable reaction conditions: sodium hydroxide in DMSO : water (1 : 9) proved to be particularly effective in preventing protonolysis. However, competing deboronation required the use of excess boronic acid (1.5 equivalents vs. aryl halide) to achieve full conversion. Gel electrophoresis of the reaction mixture revealed that Sav remained largely tetrameric and active toward biotin binding even after an SMC performed at 50 °C [see ESI Fig. S3†].

Having identified suitable reaction conditions, we screened biotinylated phosphine- and NHC ligands 1–5 combined with WT (strept)avidin (Table 1). This screening led to the identification of complexes 1, 2, and 3 as the most promising catalysts in combination with WT Sav. Despite the structural similarity between avidin and streptavidin, the result obtained with avidin was inferior to those obtained with Sav. We thus focused on Sav for further optimization studies. Past experience with other ArMs based on the biotin–streptavidin technology suggest that mutations at positions S112 and K121 (which lie closest to the...
Biotinylated metal cofactor offer a versatile means to rapidly optimize the ArM’s performance. Complexes 1–3 were thus screened with a small library of Sav mutants. The results of the chemogenetic optimization for the synthesis of 2-methoxy-1,1'-binaphthyl 8b are displayed as a fingerprint in Fig. 1, and selected results are collected in Table 2.

From these data, the following features emerge:

(a) Compared to the free cofactor, higher conversions are observed with the artificial Suzukiase. This demonstrates that the Sav host protein exerts a beneficial influence on both the activity (i.e., protein accelerated catalysis) and the selectivity.

(b) The electron-donating properties and bulkiness of the phosphine play a key role in determining the activity of the corresponding artificial Suzukiase. Accordingly, the (t-Bu)2P-bearing catalysts outperform the (Ph)2P-systems. Strikingly, both ligands 1 and 3 (Table 2, entries 10–13) show similar activity in case of S112M and S112A mutants.

(c) The enantioenriched nature of the cross-coupled product 8b strongly supports the hypothesis that the SMC is indeed catalysed by a homogeneous protein-embedded Pd-cofactor rather than Pd-nanoparticles.

(d) Varying the spacer between the biotin anchor and the P(t-Bu)2 from ethyl to propyl affords opposite enantiomers of biaryl 8b for a given Sav mutant. The best ees in favour of (S)−8b were obtained with 1−Sav K121A and 2−Sav S112M (Table 2, entries 8 and 9). These findings illustrate the versatility of chemogenetic optimization strategy: upon varying the length of the spacer the Pd-moiety experiences a very different second coordination sphere environment which is reflected in the enantioselectivity.

Having identified 1−Sav K121E as a promising first generation Suzukiase (Table 2, entry 3), we screened double mutants bearing a glutamate at position 121 (Fig. 1 and Table 2, entries 14–21):

(a) The double mutant 1−Sav S112A−K121E (Table 2, entry 20) gives better ee and TON than the single mutant Sav S112A (Table 2, entry 13). Likewise, 1−Sav S112Y−K121E gave the...
(a) The nature of the aryl halide does not influence the enantioselectivity but to lower conversions on going from iodide to bromide to chloride 6a-c (Table 3, entries 6–8).

(b) Substitution of the methoxy group by either a methyl and ethoxy group on the arylboronic acid (compare 7c to 7b and 7d) leads lower enantioselectivities (Table 3, entries 7, 10 and 12). Depending on the nature of the ortho-substituent of the aryl moiety, the CIP priorities are inverted, yielding the opposite absolute configuration (e.g. compare 8b and 8d) for the same spacial arrangement. With the exception of the biphenyl-binaphthyl 8h, all SMC products afford the same spacial arrangement using 1-S112Y-K121E Sav. We speculate that upon binding to the palladium cofactor, the bulky biphenyl group 7h forces the catalyst into a different second coordination sphere environment, leading to the opposite enantiomer (and spacial arrangement) of the coupled product.

(c) The system affords the highest enantioselectivity for binaphthyls or naphthyl-biphenyl products (albeit with the opposite chirality) in the presence of one smaller coupling partner (e.g. 6h), the enantioselectivity is significantly lower.

**X-ray structure**

To gain structural insight on the second coordination sphere around the Pd moiety, crystals of Sav S112Y-K121E were grown...

* All reactions were performed in duplicate: Δee = ±1%, Δconv. = ±5%. The absolute configuration of the product was assigned according to ref. 8. See ESI for experimental details. † After 7 days.

and soaked with a solution of 1 in DMSO (for details, see ESI†). The resulting crystals were subjected to X-ray diffraction at the beamline X06DA at the Swiss Light Source. In the resulting structure of complex 1-S112Y–K121E Sav, there is strong residual electron density in the 2Fo−Fo difference map in the biotin-binding vestibule. The Pd atom was unambiguously assigned as a strong peak in the difference map (12σ) with a corresponding peak in the anomalous difference map (8σ). The density map clearly highlights the presence of the phosphine ligand, the palladium, and the chloride (see ESI Fig. S5†). However, the cinnamyl ligand could not be resolved, likely due to disorder caused by ligand fluxionality. The amide linker exhibits two H-bonding interactions with the protein backbone: the amide nitrogen exhibits an H-bonding interaction with the side-chain of S88, and the carbonyl oxygen exhibits an H-bonding interaction with the backbone nitrogen of N49. The palladium atoms of two symmetry-related cofactors (face-to-face) are separated by 11.7 Å. The palladium was found in the vicinity of the O atoms of S112Y and K121E (Pd···O distance 6.4 Å and 7.1 Å respectively). The average B-factor of Pd is 36.10, suggesting that the complex may be fluxional or located in a shallow energy minimum (Fig. 3).

In the synthesis of chiral biaryls by the SMC, enantioselectivity is dictated by the conformation of the Pd intermediate just prior to reductive elimination. In previous DFT studies of enantioselective reductive eliminations in the SMC, it was shown that weak interactions between substrates and substrate–ligand interactions were largely responsible for biasing certain conformations and thus leading to enantioinduction. By contrast, in the 1-Sav system, it is more likely that the origin of the enantioselectivity observed is from the outer-sphere ligand effect of the protein. Inspection of the X-ray structure of the active site of 1-S112Y–K121E Sav shows that the Pd-phosphine ligand is effectively “locked” into place by the steric environment of the Sav protein, which is evidenced by the discrete atomic position of the Pd and P and their relatively low B-factors despite proximity to the solvent pocket. The restricted conformational space around the Pd atom limits certain conformations. The nearby mutated residues play an additional role. In particular, mutation of S112 to the larger tyrosine provides a significant steric barrier on the lower face of the Pd atom and is most likely responsible for the modest improvement in enantioselectivity upon mutation. Furthermore, the conformation of Y112 is effectively locked in place by an H-bonding interaction of the sidechain oxygen with the backbone carbonyl of E121 (distance 2.88 Å), which would not be the case with the similarly large S112W mutation (Table 2, entry 18). Further X-ray studies of 1-Sav with various mutations are currently underway.

It should be emphasized however that, while the X-ray structure sheds light on the position of the biotinylated catalyst precursor, we cannot exclude that the loaded catalyst, bearing the two bulky aromatic coupling partners, adopts a different position within the biotin-binding vestibule. As demonstrated recently for an artificial imine reductase, QM-MM studies may shed light on the enantioselection mechanism and the precise geometry of the transition state. In this context, reducing the cofactor flexibility by introducing stabilizing interactions with the protein has proven useful.

**Conclusions**

In summary, incorporation of an electron-rich phosphinopalladium moiety within Sav affords an artificial Suzukiase for the synthesis of enantioenriched binaphthyls (up to 90% ee and 50 TONs for 2-methoxy-binaphthyl 8b). While it is straightforward to identify aminoacids close to the cofactor, it is remains
extremely challenging to predict or rationalize why a given mutation leads to an improvement in catalytic performance. The chemogenetic optimization strategy allows to address this challenge with a limited effort: combining a small library of \( m \) mutants with a small library of \( n \) biotinylated ligands affords an \( m \cdot n \) diversity matrix. Current efforts are aimed at performing catalytic asymmetric SMC with artificial Suzukiisases \( \text{in vivo} \).
