## 1 ABREVIATION

5HT <sub>2A</sub> R	5-hydroxy-tryptamine-2A serotonin receptor
BKPyV	BK polyomavirus
BKPyVAN	BKPyV-associated nephropathy
BKPyVHC	BKPyV-associated hemorrhagic cystitis
BP	Base pairs
BRE	B recognition element
CMV	Cytomegalovirus
CNS	Central nervous system
CPE	Core promoter element
CSF	Cerebrospinal fluid
DNA	Deoxyribonucleic acid
DPE	Downstream promoter element
Ds-DNA	Double-stranded deoxyribonucleic acid
ER	Endoplasmic reticulum
ERAD	Endoplasmic reticulum-associated degradation
EVGR	Early viral gene region
HIV-1	Human immunodeficiency virus-1
HPyV10	Human polyomavirus 10
HPyV12	Human polyomavirus 12
HPyV6	Human polyomavirus 6
HPyV7	Human polyomavirus 7
HPyV9	Human polyomavirus 9
HPyVs	Human polyomaviruses
Inr	Initiation element
JCPyV	JC polyomavirus
LTag	Large tumor antigen
LVGR	Late viral gene region
MCPyV	Merkel cell polyomavirus

mRNA	Messenger ribonucleic acid
miRNA	Micro RNA
NCCR	Non-coding control region
NK	Cells natural killer cells
NLS	Nuclear localization signal
PBMCs	Peripheral blood mononuclear cells
PML	Progressive multifocal leukoencephalopathy
pRB	Retinoblastoma protein
PyVAN	Polyomavirus associated nephropathy
PyVHC	Polyomavirus associated hemorrhagic cystitis
PyVs	polyomaviruses
RNA	Ribonucleic acid
RCA	Rolling circle amplification
RPA	Replication protein A
rr-NCCR	Rearranged non-coding control region
sTag	Small T antigen
STLPyV	Saint Louis polyomavirus
SV40	Simian virus 40
TSS	Transcription start site
TSPyV	<i>Trichodysplasia spinulosa</i> polyomavirus
VLP(s)	Virus-like particle(s)
Vp1	Major capsid protein 1
Vp2	Minor capsid protein 2
Vp3	Minor capsid protein 3
ww	Wild type or Archetype

## 2 ABSTRACT

With the advent of advanced molecular biology techniques, 13 human polyomaviruses (HPyVs) have been identified from different human body compartments. Generally, infection with HPyVs is harmless in immunocompetent people. However, some of these viruses are known to cause severe morbidities in the immunosuppressed. Five HPyVs, BK polyomavirus (BKPyV), JC polyomavirus (JCPyV), Merkel cell polyomavirus (MCPyV), Trichodysplasia spinolosa polyomavirus (TSPyV) and HPyV7 are known to cause diseases. Although other HPyVs have been detected in diseased tissues or cancers, evidence of their involvement is lacking. Furthermore, less is known about the cell tropism, replication in cell culture, and gene regulation of HPyVs. The non-coding control region (NCCR) of HPyVs functions as a bi-directional promoter/enhancer system, coordinating the respective steps of the viral replication cycle. Furthermore, it also determines viral persistence, host cell specificity, replication and virulence. Efficient replication of BKPyV and JCPyV have been demonstrated in cell cultures, but less is known with regards to the novel HPyVs. NCCR activity which can be used as an indicator of HPyV cell tropism and replication in cell culture is lacking for the newly discovered HPyVs. Despite similarities in the genome organization of HPyVs, the NCCRs of the HPyVs are different with respect to large T antigen binding sites, transcriptional factor binding sites (TFBS) and length. We hypothesized that the HPyV-NCCRs will display different activity in the same or different host cells. A bi-directional reporter vector recapitulating the HPyV genome with a red fluorescence protein (dsRed2) and a green fluorescence protein (EGFP) as markers of EVGR and LVGR, respectively, was designed. The reporter was used to analyze the NCCR activity of the 13 HPyVs in different cell lines originating from kidney, skin, lungs, cervix, brain and colon cancers. Our result demonstrated that the bi-directional HPyV-NCCR activity substantially differ in the same and different host cells. Indicating that the HPyV-NCCRs differentially sense and interpret the host cells' transcription factors and different host cells' transcription factors modulate the basal HPyV-NCCRs expression. As previously reported for BKPyV and JCPyV, rearranged (rr)-NCCR variants of newly discovered HPyVs associated with diseases showed higher EVGR expression compared to their respective archetype, indicating the NCCR a major pathogenicity

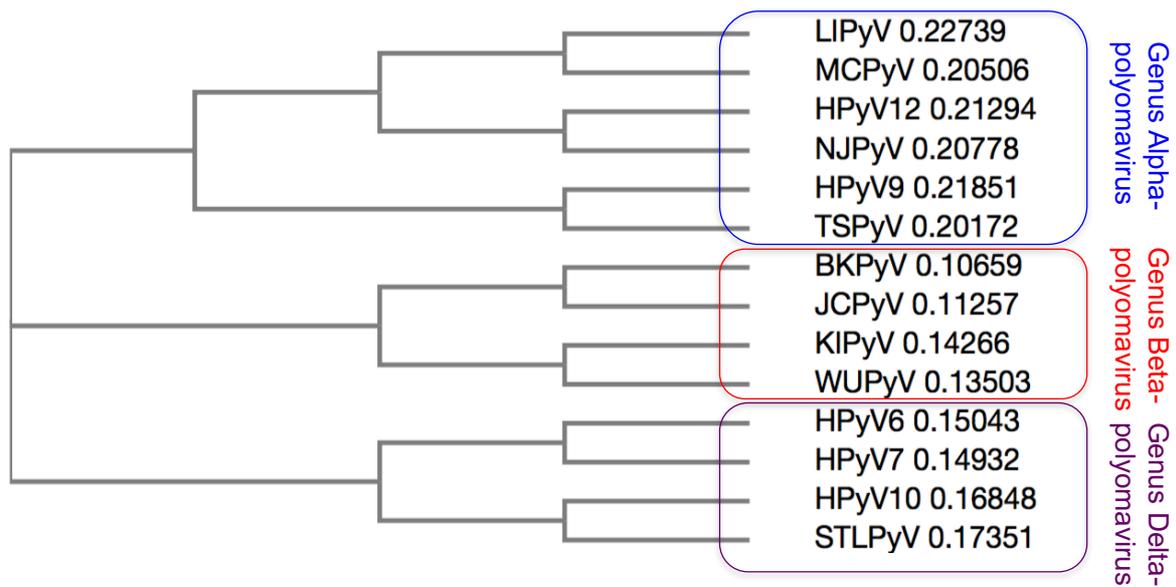

determinant. Analyzing the HPyV-NCCRs' activity in cell lines expressing T antigens (Tags) displayed activation of EVGR expression, suggesting that the bi-directional reporter recapitulates an essential NCCR response reported for the viral replication cycle. Furthermore, it indicates that cell lines expressing Tags of respective HPyVs can be used for the propagation of respective HPyVs. This data serves as a basis for understanding host and viral factors that may permit the identification of suitable cell culture systems and secondary host cell tropism for HPyVs. However, actual viral replication studies are needed to confirm replication of HPyV genomes in some of the cell lines tested. Furthermore, the role of the LTag-binding motif with regards to the regulation of EVGR and LVGR has been well-characterized in the monkey polyomavirus, simian virus 40, although very little is known with respect to the role of the LTag-binding motif for HPyVs. Given that the LTag recognition sites influence EVGR and LVGR expression and the LTag-binding sites organization of SV40 is similar to that of some HPyVs, such as BKPyV, we hypothesized that the role of the LTag-binding motif in the regulation of EVGR and LVGR expression in BKPyV is potentially similar to that of SV40. The EVGR and LVGR expression of BKPyV archetype (ww)-NCCR was compared with those of BKPyV ww-NCCR defective in one or more LTag-binding motifs in HEK293, HEK293T and HEK293TT cell lines, expressing none, small and large amounts of SV40 LTag, respectively. Our results indicated that abundant LTag decreased EVGR-expression by probably interacting with LTag binding *site A*, suggesting abundant LTag expression may down regulate EVGR expression, similar to SV40's-EVGR autoregulation. Contrarily, the LVGR expression is proportionally increased in the presence of increasing amounts of LTag expression (HEK293T and HEK293TT cells), by LTag potentially interacting with binding *sites A* and *D*. These results may open avenues for designing new therapeutic strategies targeting this reduction of EVGR expression in the presence of abundant LTag expression. Actual viral replication studies are needed to verify whether these mutants are replicative competent or not.

Concluding, a basic approach was used to elucidate factors that may allow the replication of HPyVs in cell cultures, that will greatly enhance our understanding of the basic biology of these viruses. Furthermore, putative host cell tropism of HPyVs was suggested. The effect of LTag-binding sites with respect to BKPyV's EVGR and LVGR expression, which could be extrapolated to other HPyVs was shown.

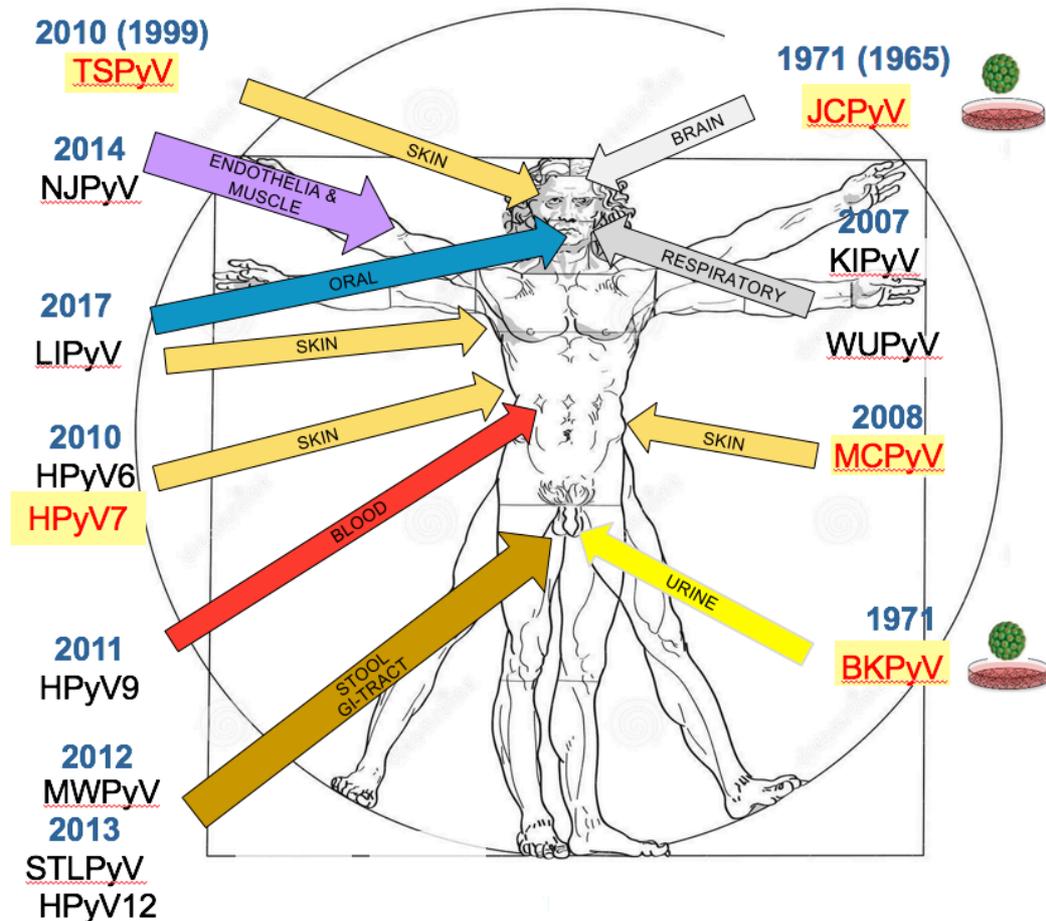

### 3 INTRODUCTION

#### 3.1 *Polyomaviridae*

Polyomaviruses (PyVs) belonging to the family *Polyomaviridae* infect a wide range of vertebrates from birds to mammals. However, PyVs are limited in the species they can productively infect (1). The *Polyomaviridae* Study Group of the International Committee on Taxonomy of Viruses has recently revised the family *Polyomaviridae* by a sequence- and host-based rationale (1). Based on the observed distance between large T antigen (LTag) coding sequences, at least 73 species of the family *Polyomaviridae* were classified into four genera (Alpha-, Beta-, Gamma- and Delta-polyomavirus) (2). The Alphapolyomavirus and Betapolyomavirus genera contain polyomaviruses that infect a variety of mammals. The gammapolyomavirus genus contains avian polyomaviruses, while the genus Deltapolyomavirus contains only four human polyomaviruses (HPyVs). The observed distance between LTag-coding sequence of HPyVs is shown (**Fig. 1**). However, the closest neighbor of a HPyV may be from a PyV from animals. At least 73 PyVs have been identified so far, of which 13 are HPyVs detected in different human-body compartments (**Fig. 2**) (2). Specifically BK polyomavirus (BKPyV) (3), JC polyomavirus (JCPyV) (4), Karolinska institute polyomavirus (KIPyV) (5), Washington university polyomavirus (WUPyV) (6), Merkel cell polyomavirus (MCPyV) (7), human polyomavirus 6 (HPyV6) (8), human polyomavirus 7 (HPyV7) (8), *Trichodysplasia spinulosa* polyomavirus (TSPyV) (9), human polyomavirus 9 (HPyV9) (10), human polyomavirus 10 (HPyV10) (11), St. Louis polyomavirus (STLPyV) (12) human polyomavirus 12 (HPyV12) (13), New Jersey polyomavirus (NJPyV) (14). While this work was in progress, the International Agency for Research on Cancer (IARC) in Lyon described a new PyV (LIPyV), which now needs confirmation as a HPyV (15). HPyVs generally cause asymptomatic infections in early childhood, which can then reactivate upon immunosuppression causing severe diseases. Of all these HPyVs, only BKPyV, JCPyV, MCPyV, TSPyV and HPyV7 are known to cause diseases (Fig. 2). The seroprevalence of HPyVs is up to 99% in the general adult population (Table 1) (16-18), suggesting a low-level infection of these viruses in the general population.

**Fig. 1:** A neighbor joining phylogenetic tree without distance corrections based on observed distance between HPyVs large T antigen coding sequences. The phylogram was constructed after multiple sequence alignment of the large T antigen sequences of the HPyVs using clustal omega. Next to each branch the evolutionary distance is depicted. Based on the tree, HPyVs could be grouped under 3 genera (Alpha-, Beta- and Delta-polyomavirus). GenBank accession numbers, from which the large T antigen sequences are based are found in table 6.

**Fig. 2:** The 13 HPyVs identified from different compartment of the human body including LIPyV which was discovered recently but needs confirmation as a HPyV (indicated with the arrows). The year of identification of each HPyV is depicted. Only 5 HPyVs highlighted in yellow can cause diseases. BKPvV and JCPyV are the two HPyVs that can be efficiently propagated in cell culture.

### 3.1.1 Structure and genome architecture of polyomavirus

Polyomaviruses are non-enveloped viruses with a supercoiled double-stranded circular DNA genome of about 5000 base pairs (bp). The genome is associated with cellular histones to form a minichromosome. It is encapsidated in an icosahedral-shaped viral capsid of approximately 45 nano meter (nm) in diameter (19, 20). The capsid is made up of 72 pentamers of the major capsid protein, viral protein 1 (Vp1), which is capable of self-assembly into viral-like particles (VLPs) (19, 21). Each Vp1 pentamer is associated with a minor capsid protein, Vp2 or Vp3 (**Fig. 3A**). The genome of polyomaviruses is divided into 3 main regions, the non-coding control

region (NCCR) and two transcriptional regions; early viral gene region (EVGR) and the late viral gene region (LVGR) (**Fig. 3B**). They are termed EVGR and LVGR due to the time of transcription during the course of the viral replication cycle. The EVGR and LVGR are transcribed in opposite strands and directions by the host cell RNA polymerase II as a single pre-messenger RNA.

#### 3.1.1.1 Non-coding control region

The NCCR functions as a bi-directional promoter, harboring the origin of viral replication (ori), early and late promoters, enhancers regions, transcriptional start sites and a multitude of transcription factor-binding sites (TFBS). The NCCR can be referred to as the “brain” of polyomaviruses. It is defined as the region between the start codon of the LVGR and the start codon of the EVGR. In BKPyV and JCPyV, the NCCR region proximal to the LVGR contains enhancer elements, LVGR transcriptional initiation sites and usually undergoes rearrangements including deletions, duplications and point mutations (22), whereas the region proximal to the EVGR harbors the origin of viral genome replication, EVGR transcriptional initiation sites and mostly not rearranged (23). This region also contains palindromes and dyad symmetry elements (23). Rearrangements of NCCR region proximal to the LVGR region result in different strains of the same species, which confers tissue specific expression of EVGR and LVGR expression. Rearranged BKPyV and JCPyV NCCR variants are common in BKPyV- and JCPyV-associated diseases (24-26). Nonetheless, BKPyV-induced hemorrhagic cystitis and nephropathy was not linked to any particular NCCR architecture (27). Furthermore, polyomaviruses containing similar NCCR rearrangement have been reported in different patient groups and healthy individuals (18, 28). The exact role of rearranged NCCR variants in pathogenesis and the mechanisms of generating the rearrangements are poorly understood. Rearranged BKPyV and JCPyV NCCR variants with diverse duplications and deletions from patients, have been reported to increase EVGR expression, replication capacity and cytopathology in vitro (25, 26). This suggests that BKPyV and JCPyV variants with rearranged NCCR can be linked to increase EVGR expression, replication capacity and disease (22, 25), which has not been studied for the novel HPyVs. A multitude of TFBS within the HPyV NCCR control the cell specific EVGR and LVGR expression of HPyVs. The roles of some of these TFBS in the

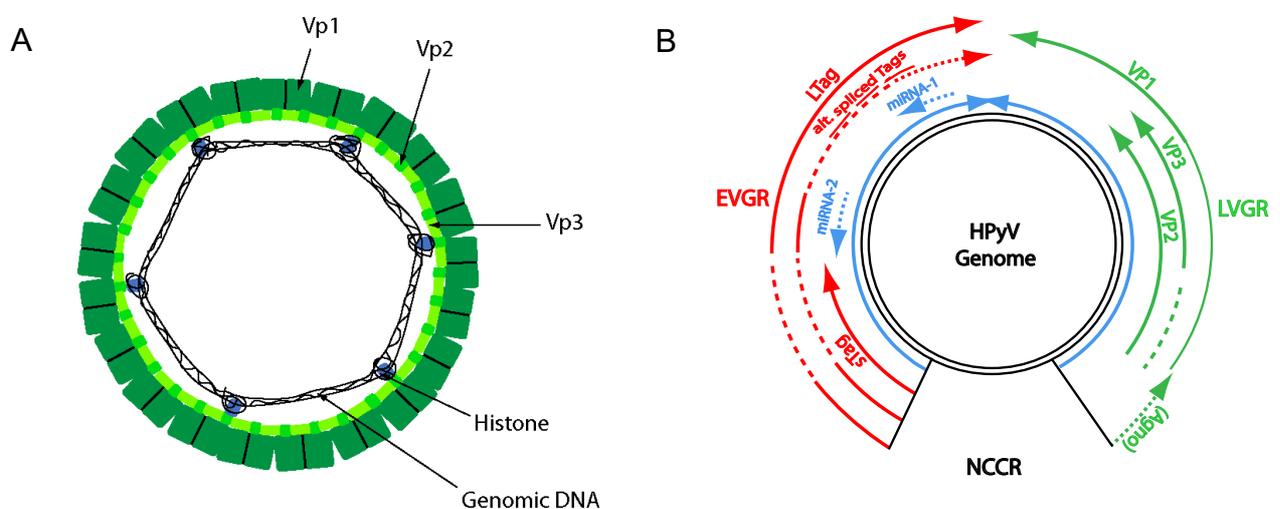

control of BKPyV and JCPyV gene expression are known (29-34), whereas little or no information is known with respect to the newly discovered HPyVs. Nonetheless, since some of the TFBS are conserved among HPyVs, the knowledge gained from BKPyV and JCPyV can be extrapolated to the other HPyVs.

### 3.1.1.2 Early viral gene region

The EVGR pre-mRNA is spliced into different variants encoding for large T antigen (LTag), small T antigen (sTag) (**Fig. 4**) and other T antigens variants, which are produced by alternative splicing. Some of the HPyVs encode additional early proteins. BKPyV encodes 17kT, JCPyV; T'135, T'136 and T'165, MCPyV; 57KT and ALTO, TSPyV; tinyT, 21kT, MTag and ALTO HPyV9; 145T, STLPyV may encode 229T, HPyV12; 84T and NJPyV may encode 299T (18).

### 3.1.1.3 Late viral gene region

The LVGR encodes the viral structural proteins, Vp1, Vp2, Vp3 and a non-structural late protein, agno, which are produced by alternative translational start sites. Only simian virus 40 (SV40), BKPyV and JCPyV encode the late non-structural protein, agno. The capsid of PyVs are composed of 72 pentamers of the major capsid protein Vp1, which are strengthened by disulphide and calcium bridges, and conserved throughout the polyomavirus family (20). These Vp1 pentamers form barrel-like structures, and within the hollows of Vp1, are contained minor capsid proteins, Vp2 and Vp3.

**Fig. 3:** (A) Schematic representation of the HPyV viral particle. (B) Representation of general features of the HPyV genome.

### 3.1.2 Polyomavirus life cycle

#### 3.1.2.1 Host cell receptors, viral entry and un-coating

The detailed mechanisms of polyomavirus entry, trafficking through the cytoplasm and nuclear entry is not well understood. However, much of the understanding of the polyomavirus life cycle (**Fig. 5**) have been deduced from investigating SV40, BKPyV and JCPyV infection mechanisms (35). Vp1 is known to interact with the host cell receptors, as for instance mutation of the Vp1 calcium binding residues block viral entry into the host cell, resulting to disruption of virion assembly (36). The monkey polyomavirus, SV40 binds the monosialotetrahexosylganglioside (GM1) receptor and enters the cell via caveolar-mediated endocytosis. Additionally, SV40 can also independently enter the cell via caveolin or clathrin mediated endocytosis (37). On the other hand, BKPyV uses the disialoganglioside GT1b and trisialogangliosides GD1 as receptors to enter the cells by caveolar-mediated endocytosis, while JCPyV binds to serotonin 5-hydroxytryptamine 2A (5-HT<sub>2A</sub>) and enters the cell via clathrin-mediated endocytosis (38, 39). After internalization, the viral particle is trafficked through the microtubule network to the endoplasmic reticulum (ER) (40-42). ER transiting is unique to PyVs, no other DNA virus known to replicate in the nucleus uses this route. Interactions between the PyVs capsid proteins and the ER proteins have been well studied in SV40 (43). Partial un-coating of the viral particle takes place in the ER. The disulfide-isomerase unlinks the disulfide bonds between the Vp1 pentamers in the capsid (40, 44). The minor capsid proteins Vp2 and Vp3 become accessible with the help of chaperone proteins, which is important for subsequent steps in the viral life cycle. Once the viral particle is partially disassembled, it is then retrograde-transported from the ER to the cytoplasm via the ER associated degradation (ERAD) pathway. The viral particle is then guided into the nucleus via the nuclear pore with the help of the nuclear localization signal (NLS) present in Vp2 and Vp3 (45).

#### 3.1.2.2 Early viral gene expression

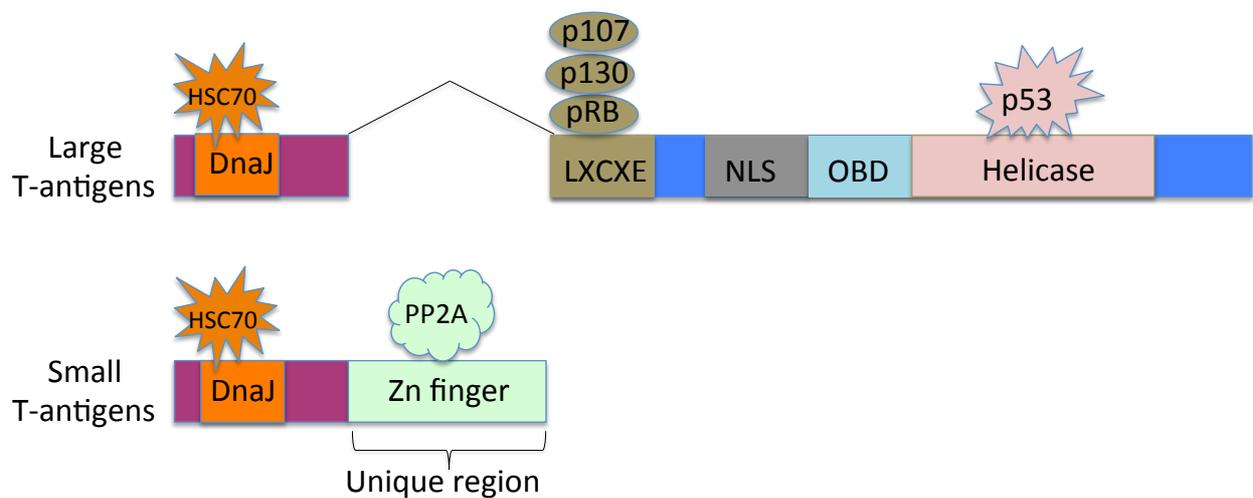

The early and late promoters within the NCCR control the bidirectional EVGR and LVGR transcription. The EVGR and LVGR transcription progresses outward from the NCCR via opposite strands of the genome. Once the virus gets into the nucleus, EVGR transcription is initiated by cellular RNA polymerase II and controlled by cis-acting sequences within the NCCR, such as TATA box, GC-rich sequences and enhancers. A single pre-EVGR mRNA is produced which undergoes alternative splicing into sTag, LTag and other T antigens spliced variants. The T antigens' coding regions are overlapping at the N-terminal sequence, but differ at the C-terminal sequence (46).

#### 3.1.2.2.1 Large T antigen: the multifunctional protein

The LTag of HPyVs is a multifunctional protein that interacts with numerous cellular and viral factors to initiate viral gene expression and viral genome replication (1). The structure and functions of the LTag have been largely described in the SV40 model, which is also relevant for BKPyV and JCPyV with amino acids homology of approximately 81% between SV40 and BKPyV, and 79% between SV40 and JCPyV (47). The large T antigen contained five regions that are conserved among HPyVs, that is, DnaJ region, LXCXE motif, nuclear localization signal, origin-binding domain (OBD) and ATPase/helicase domain. LTag binds to pentanucleotide sequences, GRGGC or its complement GCCYC at the ori via the OBD region (48). The NCCR of all HPyVs contains at least one of these pentanucleotide sequences (49). Large T antigen binds to the ori within the NCCRs, unwinds the duplex DNA viral genome by using the ATPase/helicase activity (48). The ATPase gives the energy required for the helicase activity, while a zinc-binding domain proximal to the helicase domain is needed for the formation of LTag hexamer at the ori (48). In addition, LTag drives the cell into S-phase of the cell cycle resulting in the activation of DNA damage response (DDR) in order to promote replication of viral genome. The DnaJ domain cooperates with a proximally located motif called LXCXE to bind the retinoblastoma tumor suppressor proteins, pRB/p130/p107 (48). This binding disrupts the interactions between E2F (E2 transcription factor) and pRB/p130/p107. Dissociating pRB from E2F permits the formation of E2F-E2F dimers, which interacts with its target sequence and drives S-phase progression and DNA synthesis (48). Normally, improper entry of the host cell into S-phase would signal a p53-mediated apoptosis.

However, to circumvent the p53-mediated apoptosis, LTag binds p53 via the P53-binding domain within the helicase domain of LTag and allows progressive viral replication (1, 50). This p53 protein is a critical tumor suppressor in humans and its involvement in tumorigenesis has been widely demonstrated in the SV40 model (48, 51).

Likewise, sTag also has tumorigenic potentials. It promotes cells growth and viral replication by interacting with protein phosphatase 2A (PP2A), and disrupts its phosphatase ability (52). It has been reported to stimulate intercellular kinases to also promote cellular growth pathways (53).

**Fig. 4:** Schematic representation of the large and small T antigens.

### 3.1.2.2.2 Viral encoded microRNA

During the viral life cycle, small noncoding RNAs (miRNAs) post-translationally regulate gene expression by directed-mRNAs cleavage or repression of translation. SV40, BKPyV, JCPyV, and MCPyV encode miRNA that target and deplete early viral transcripts, such as LTag mRNA (54-56). SV40 miRNA mutant infected cells were observed to be more sensitive to T antigen specific cytotoxic T-cell lysis in vitro, suggesting the importance of miRNA in viral evasion of the host immune response. However, similar amounts of infectious virions were produced with the SV40 miRNA mutant compared to the wild-type (55). Moreover, the stress-induced ligand, UL16 binding protein 3 (ULBP3), which is important in the activation of the natural killer T-cell receptor (NKG2D), has been reported to be targeted by BKPyV and JCPyV

miRNA (57). The NKG2D mediated killing of infected cells was reduced due to the downregulation of ULBP3 by the viral miRNA. This indicated that PyVs could use this mechanism to latently infect the host without being eliminated by the host immune system (57). Interestingly, archetype (ww) BKPyV encoded miRNA has been reported to be involved in limiting BKPyV ww replication in renal tubular epithelia cells (58). Nevertheless, regulation of the miRNA could be accomplished through the balance of regulatory elements within the NCCRs controlling EVGR and miRNA expression prior to genome replication (58). The BKPyV and JCPyV miRNA is encoded on the late strand with complementarity to the 3' coding end of the T antigen mRNA (Fig. 2B) (54). Since the miRNA is located on the late strand, one could suggest that the miRNA is expressed from the late promoter, although it may also be expressed from within or outside the NCCR. The miRNA of BKPyV and JCPyV are identical; this indicates that in the case of co-infection, the miRNA from each virus can downregulate each other's T antigens expression. Since PyVs use miRNA to evade the host immune system, therapeutically targeting miRNA could be used for treating PyVs-associated diseases. Therefore, investigating the presence and function of miRNA of the other HPyVs is warranted.

### 3.1.2.3 Viral genome replication

PyVs depend on the host cell machineries to replicate its genome. LTag coordinates viral genome replication by recruiting multiple host factors required for viral genome replication. LTag monomers bind to the viral ori and assemble into two hexamers. Once the binding to ori occurs, LTag uses its helicase activity to unwind the double stranded DNA (48) (as explained above). Next, replication protein A (RPA) is recruited to bind the single stranded unwound DNA, to prevent it from annealing and forming secondary structures.

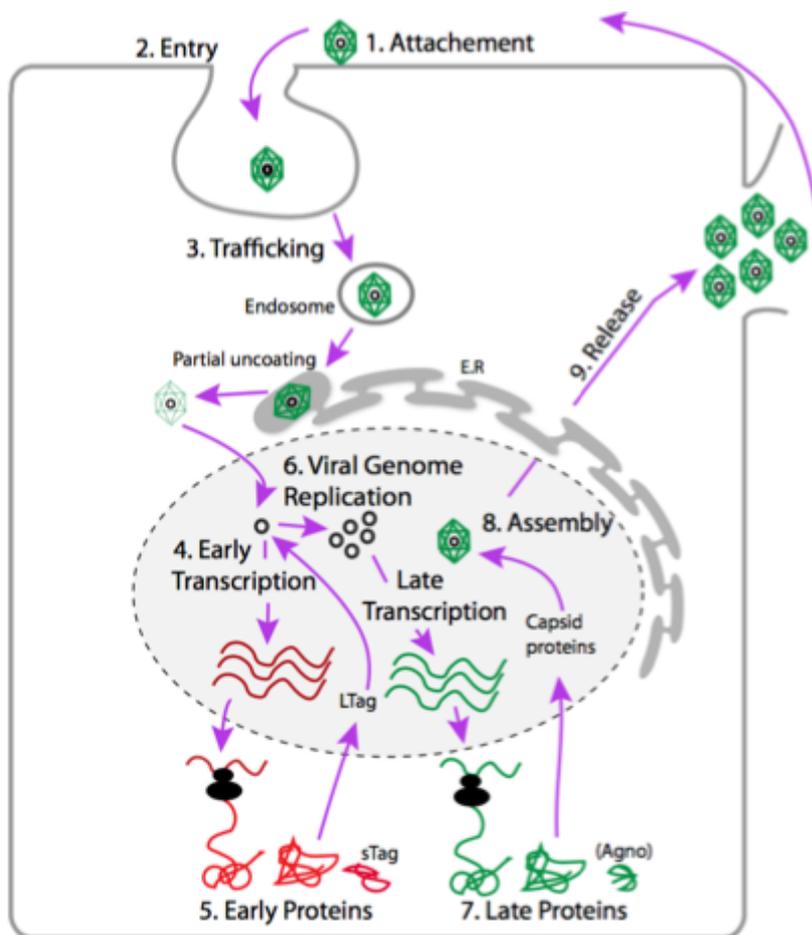

### 3.1.2.4 Late viral gene expression

Concomitantly to viral genome replication, late viral proteins are expressed. LTag begins suppression of EVGR expression at this point, but the exact mechanism is not well understood. It is suggested that, high LTag amounts binding the ori, particularly to LTag binding *site I* in SV40 (59), results in the downregulation (auto-regulation) of EVGR expression and promotion of LVGR expression. Additionally, miRNA could

also be involved as explained above. LVGR transcription produces at least 3 structural proteins, Vp1, Vp2 and Vp3. They are encoded in an overlapping manner; Vp3 is completely encoded in the 3' end of Vp2. SV40 has been reported to encode Vp4 (60). Furthermore, unlike the other HPyVs the LVGR of SV40, BKPyV and JCPyV encodes a small late non-structural protein called agno (6, 7, 61, 62).

#### 3.1.2.5 Encapsidation and viral release

In baculovirus expression systems, Vp1 can self-assemble into the capsid protein without the presence of Vp2 and Vp3, but Vp1 cannot assemble into the capsid protein in the cytoplasm, which might be due to low calcium concentrations in the cytoplasm. This theory was supported by the higher calcium concentration in the nucleus, where virions were observed by confocal and electron microscopy (19, 21, 63). The LVGR capsid proteins made in the cytoplasm are transported to the nucleus with the help of the nuclear localization signal sequence within the proteins (NLS). Once in the nucleus they are assembled into virions. Vp1, the major capsid protein associates with minor capsid proteins Vp2 or Vp3 (not encoded by MCPyV), which extend internally anchoring the minichromosome. Viral release of the fully assembled infectious particles is poorly understood, but thought to occur via a number of processes including host cell lysis, agnoprotein increasing membrane permeability, Vp3 lytic properties, SV40 Vp4-mediated viroporin release (60, 64, 65). Vp4 was reported to be encoded by SV40 and function as a viroporin to form pores for viral release (60). However, recently, Henriksen et al. demonstrated that Vp4 is not important for viral release, since there wasn't any difference between wild-type and Vp4 mutant release (66).

**Fig. 5:** Schematic representation of polyomavirus life cycle. **1.** Attachment of host-cell receptors. **2.** Entry by endocytosis. **3.** Transport of viral particle via endosomes to ER and later to the nucleus via the nuclear pore. **4 and 5.** EVGR transcription and translation. **6.** Nuclear translocation of LTag and viral genome replication. **7.** LVGR transcription and translation. **8.** Newly-synthesized viral genomes encapsidation. **9.** Infectious viral particles release.

### 3.1.3 The emerging family of polyomaviruses

#### 3.1.3.1 Murine polyomavirus

The mouse polyomavirus (MPyV) was one of the first PyV to be isolated by Ludwig Gross in 1953 while studying murine leukaemia virus (67). Heat inactivation of an inoculum, which usually protects against infection with Murine leukaemia virus, still resulted in leukaemia and tumors in the parotids glands of newborn mice. Thus, he concluded that the tumor was due to another infectious agent. Gross named this

infectious agent after further experimentation “polyoma” due to its ability to cause multiple tumors in various tissues in newborn mice. Since the MPyV discovery, viral oncogenesis has been intensively studied (46).

### 3.1.3.2 Simian Virus 40

SV40 was discovered in 1960 as a contaminant of a batch of polio vaccines generated in primary kidney cells from Rhesus monkeys (68). Between 1955 and 1963 approximately 100 million adults and children received the polio vaccine and the same methods for generating the vaccine were used throughout the world. A vacuolating agent, later named Simian virus (SV40) was identified during safety testing in some cultures causing cytopathic effect (1, 68). Furthermore, investigations of culture systems infected with SV40 revealed that this virus had the ability to cause tumors in animal models (69). SV40 has been linked to non-Hodgkin lymphoma, adult and pediatric brain tumors, mesothelioma, and osteosarcoma (70). Epidemiological studies show that populations exposed to the SV40-contaminated polio vaccine failed to show increased risk of tumor development (71-73). However, the understanding of cell cycle and oncogenic pathways that permit the discovery of tumor suppressors pRB and p53 was greatly improved due to SV40 research (1, 46, 74). For more than 50 years the question of whether SV40 infection is an agent of human cancer has remained highly controversial (75).

### 3.1.3.3 Human Polyomaviruses

#### 3.1.3.3.1 BK and JC polyomavirus

BKPyV and JCPyV were the two HPyVs discovered in 1971. They were named after the initials of the two patients from whom the viruses were isolated (3, 4, 76). BKPyV was isolated from the urine of a kidney transplant recipient (3), while JCPyV was isolated from the brain tissue of a progressive multifocal leukoencephalopathy (PML) patient (3, 4, 76). Inoculating human fetal brain tissue with isolated JCPyV agent revealed that JCPyV was the causative agent of PML, a fatal demyelinating disease in the central nervous system (CNS) (4). Infection of BKPyV and JCPyV occurs during early childhood. Seroprevalence of BKPyV and JCPyV in the general adult population ranges from 50-98% (77). The mechanism of transmission of BKPyV and

JCPyV is poorly understood, but thought to be via the respiratory or fecal-oral route (78-80). After primary infection of BKPyV or JCPyV, the viruses establish a persistent infection, possibly in kidney, neuronal, hematopoietic or lymphoid tissues (81-83). BKPyV has been detected in various organs/compartments of the human body; peripheral blood mononuclear cells (PBMCs), brain cells, urogenital cells, lymphocytes, cervix, rectum, sperm, skin and numerous cancers such as, neuroblastoma, osteosarcoma, prostate, cervix and Kaposi's sarcoma (84-87). JCPyV has been detected in PBMCs, kidney, lungs, bone marrow, gastrointestinal tract, tonsils, and lymphoid organs and in various cancers such as, B-cell lymphoma, lung, colon, urothelial, prostate, esophageal and cancers of the CNS (88-91). Reactivation of JCPyV and BKPyV can occur upon immune suppression. The incidence of PML has increased greatly with the pandemic of acquired immunodeficiency syndrome (AIDS) in the 1980s (90). BKPyV reactivation occurs mostly in renal transplant recipients resulting in nephropathy, which is associated with the risk of organ rejection (90, 92-94). Reactivation of BKPyV in bone marrow transplant (BMT) recipients could lead to hemorrhagic cystitis (95, 96). Both viruses are known to have four main serological subtypes, however, the clinical importance of these subtypes is poorly understood (97)

#### 3.1.3.3.2 KI and WU polyomavirus

Approximately 36 years after the discovery of the first two HPyVs, the interest in human polyomaviruses was rekindled in 2007, when two new HPyVs, KIPyV and WUPyV, were discovered (6, 62). Similar to the initial detection of BKPyV and JCPyV, KIPyV and WUPyV were reported within one month of each other. Using large-scale molecular virus screening, KIPyV was detected in a respiratory secretion at the Karolinska institute (KI) by Allander et al. Within a month, Gaynor et al., identified WUPyV in a respiratory secretion from a child with clinical signs of pneumonia at the Washington University (WU) by using high throughput molecular sequencing techniques (6, 62). Furthermore, these viruses were also detected in respiratory secretions of children with acute respiratory illness (98). Since then, they have also been detected in blood, faces, urine, lung, tonsils, cerebrospinal fluid, spleen, lymphoid tissue, brain of HIV-infected patients with and without PML (99-102). Both viruses are phylogenetically related to each other and belong with BKPyV and

JCPyV to the Genus *Betapolyomavirus* (2, 6). The detection rates of both viruses in respiratory secretions by polymerase chain reaction (PCR) were between 0.4%-9% in studies conducted throughout the world (5, 6, 62, 98, 103-116). Detection rates in immunocompromised populations are estimated to be higher, and many of the reports lack appropriate control population and used small cohorts. The detection of KIPyV and WUPyV with other respiratory pathogens is common, thus making it difficult to draw the etiological link between these two viruses with respiratory illnesses (6, 62, 116, 117). The seroprevalence of KIPyV and WUPyV in healthy adults' ranges between 55%-93.3% and 54%-90%, respectively. This suggests a wide spread of KIPyV and WUPyV infection (77, 118, 119). Like BKPyV and JCPyV, it is hypothesized that KIPyV and WUPyV may persist in their host, reactivate and cause disease in immunosuppressed individuals. So far, no study has shown a significant difference between KIPyV and WUPyV detection rates in immunocompetent or immunocompromised individuals, although higher viral loads of KIPyV have been reported in the immunocompromised host (101, 120-127). Currently, no possible link of KIPyV and WUPyV to cancer has been made. Moreover, a role for both viruses in different cancer types is possible (128-130). Lastly, there have been no definitive association of these viruses with any disease.

#### 3.1.3.3.3 Merkel cell polyomavirus

One year later (2008), Merkel cell polyomavirus (MCPyV) was detected using a digital transcriptome subtraction technique of RNA extracted from a Merkel cell carcinoma (MCC) (7). MCC is rare and aggressive skin cancer predominantly found in elderly and immunocompromised individuals. 50% of individuals with advanced cases live at least 9 months after being diagnosed with MCC, which is greatly reduced in the immunocompromised (7, 131). Compared to SV40, the genome of MCPyV has higher sequence homology to Lymphotropic polyomavirus (LPyV), a polyomavirus isolated in 1979 from a B-lymphoblastoid African green monkey cell line. DNA of MCPyV has been detected in the peripheral blood of both healthy and immunosuppressed individuals and many other human samples/organs such as: eyebrow hairs, gall bladder, oral samples, lung, tonsils, intestine, appendix, liver, blood, saliva, lymphoid tissue, urine, malignant and non-malignant tonsillar tissues (132-137). Unlike other HPyVs, MCPyV is more closely related to MPyV.

Nonetheless, T antigens of MCPyV have the conserved features of the other HPyVs including; DnaJ binding domain, OBD, helicase/ATPase domain and conserved pRB binding motif (7). The seroprevalence of MCPyV in the healthy adult population ranges between 25%-42% (77). MCPyV was initially found integrated into the human genome (7). Viral integration into the host genome has also been reported for other polyomaviruses that cause tumor in cell culture models, but not before the discovery of MCPyV (7).

#### 3.1.3.3.4 Human polyomavirus 6 and 7

Two new HPyVs were identified on the skin of adults in 2010 (8). HPyV6 and HPyV7 were detected by rolling circle amplification (RCA) from forehead swabs of volunteers (8). Small amounts of HPyV6 and HPyV7 virions are shed from skin of infected individuals. Some initial investigations detected 5/35 people to be positive for HPyV6 and 4/35 positive for HPyV7. These viruses have been detected in cervical specimens of HIV infected and non-infected, malignant and non-malignant tonsillar tissues, respiratory samples, feces and urine of an allogeneic stem cell transplant recipient. LTag of HPyV7 has been found in 23/37 thymomas (62.2%) and 8/20 thymic hyperplasia (40%) tissues. Furthermore, HPyV7 have been detected in PBMCs and skin of single and double lung transplant recipients with pruritic rash (133, 138-140). In addition, both viruses were detected in immunosuppressed patients with pruritic and dyskeratotic dermatoses (141). This suggests that these viruses can cause disease in immunocompromised patients. Seroprevalence studies using VLPs revealed that, HPyV6 and HPyV7 infect 69% and 35% adults, respectively, indicating that exposure to these viruses is common (8). So far definitive association of these viruses to tumorigenesis is unknown (142).

#### 3.1.3.3.5 *Trichodysplasia spinulosa* polyomavirus

In 2010, another human polyomavirus called TSPyV was detected on the skin by RCA (9). TSPyV is the causative agent of *Trichodysplasia spinulosa* (TS) (9). TS is a rare skin disease affecting mostly immunocompromised persons (9, 143). The virus together with HPyV9, HPyV12, MCPyV, NJPyV and LIPyV belong to the genus *Alphapolyomavirus* (Fig. 1) (2). The clinical development of TS occurs as an eruption of erythematous papules with many follicular extensions localized in the limbs and

central face, mostly the nose (144), which was initially reported by Izakovic et al from a 31-year-old kidney transplant recipients undergoing treatment with cyclosporine A (145). Using quantified PCR and electron microscopy (EM) demonstrated that TSPyV was actively infecting TS follicular biopsy (144, 146). It has also been detected in 4% of skin swabs from kidney transplant recipients without clinical TS, indicating that this virus could be found on the skin without causing disease (9). In addition, this virus has been detected in renal allograft of a kidney transplant patient, heart, spleen, lung, colon, bronchus, small intestine, liver, respiratory samples, feces, tissue from a patient with myocarditis and in tonsillar tissues of healthy individuals (138, 147-149). TSPyV has high seroprevalence of about 70% in adult populations (150). This supports the theory that infection with this virus is usually asymptomatic causing TS only in highly immunocompromised individuals (150).

#### 3.1.3.3.6 Human polyomavirus 9

In 2011, HPyV9 was detected in the serum of a kidney transplant recipient using degenerate primers (10). Whole genome sequencing of HPyV 9 revealed it to be closely related to LPyV and contained all the typical genomic characteristics of a polyomavirus (10). LPyV has been detected in blood in both immunosuppressed and healthy people and has a seroprevalence of 30% (77, 151, 152). A seroprevalence of 40% was determined for HPyV9, although cross reactivity of LPyV and HPyV9 was confirmed (153). This cross reactivity may account for the previous serological evidence of LPyV in human infection (153, 154). HPyV9 has been detected on skin swabs of MCC patients. This is in accordance with the finding that in MCC patient groups, HPyV9 was more common compared to age-matched controls (154). Furthermore, HPyV9 variant was detected in PBMCs of an AIDS patient (155).

#### 3.1.3.3.7 Human polyomavirus 10

HPyV10 was discovered in 2012 in chondyloma specimens from a patient with warts, hypogammaglobinemia, infections, and myelokathexis-congenital disorder of leukocytes (WHIM) syndrome (11, 156). In the same, year a strain of HPyV10 termed Malawi polyomavirus (MWPyV) was detected in stool samples of healthy children from Malawi using shot gun 454 pyrosequencing (11). Another nearly genetically identical strain called Mexican polyomavirus (MXPpyV) was detected in stool samples

of Mexican children (157). MWPyV strain was also found in one respiratory sample and stool samples from healthy Mexican children. Furthermore, MWPyV was found in tonsils and adenoids of healthy children, whereas HPyV10 was also detected on skin of HIV-infected and non-infected men suggesting skin tropism for HPyV10 (157, 158).

#### 3.1.3.3.8 St Louis polyomavirus

Like MWPyV, STLPyV was detected in a stool sample from a healthy child in 2013 using 454 pyrosequencing (12). STLPyV is placed in the genus *Deltapolyomavirus* (2). The virus shows high sequence homology to HPyV6, HPyV7 and HPyV10 in the LTag coding sequence (2). STLPyV has been reported to encode a unique protein called 229T, obtained through alternative splicing of the EVGR pre-mRNA (18). Stool specimens collected from children confirmed the presence of STLPyV, however there was no statistical association between STLPyV and gastroenteritis. STLPyV has also been identified from a skin wart of a WHIM syndrome patient (12, 159). Compare to other HPyVs, STLPyV has a high seroprevalence of about 68%-77%, with age-stratified data indicating early childhood acquisition of this virus (160).

#### 3.1.3.3.9 Human polyomavirus 12

HPyV12 was detected in resected human liver tissues and also in rectum, colon and a fecal sample (13). Studies in healthy adults/adolescents and pediatric children revealed a seroprevalence of 23% and 17%, respectively (13), indicating that primary infection of HPyV12 occurs during early childhood. So far, this virus has not been associated with any disease.

#### 3.1.3.3.10 New Jersey polyomavirus

NPyV was detected in endothelial cells of a pancreatic transplant recipient suffering from necrotic plaques on multiple areas of the skin and retinal blindness (14). High viral load and viral particles of NJPyV within the nuclei of vascular endothelia cells were detected by specific real time PCR and EM (14). Reduction of immunosuppression resulted to slow subsiding of the patient's weakness, but the patient's eyesight failed to return. NJPyV viremia was detected until 10 months after the onset of symptoms, even though the patient showed improvement of symptoms. Furthermore, it was not possible to detect NJPyV in sera collected from the general

population or in the patient's pre-transplant serum (14).

#### 3.1.3.3.11 Lyon IARC polyomavirus

The most recently LIPyV was discovered from the skin swabs, oral gargles and an eyebrow hair of cancer-free individuals by using a sensitive degenerative PCR and next-generation sequencing (15). The virus is phylogenetically related to the raccoon PyV identified in neuroglial tumors in free-ranging raccoons. The biological properties of this PyV is yet unknown.

**Table 1:** HPyVs discovery and potential and proven associated-diseases. N.A: not applicable.

Species/ common Name	Year discovered/ references	Initial biological compartment isolated/detected	another biological compartment detected	Associated-diseases	Seroprevalence / references
BKPyV/ HPyV1	1971 (3)	Urine of kidney transplant recipient	Bladder, blood, bone, brain, CNS, heart lung, skin, spleen, genital, salivary glands	BKPyV associated- hemorrhagic cystitis (BKPyVHC) (96), BKPyV associated-nephropathy BKPyVVAN) (161), progressive multifocal leukoencephalopathy (PML) (162), retinitis (162), pneumonitis (163) meningitis and encephalitis (164), ureteral stenosis (165), prostate cancer (166),	55–90% (77, 167)
JCPyV/ HPyV2	1971 (4)	CSF of a PML patient	Brain, CNS, kidney, lungs, GI tract, blood, tonsils	PML (4), colon cancer (168), multiple sclerosis (MS) (169)	44-90% (77, 167)
KIPyV/ HPyV3	2007 (62)	Respiratory tract secretions	Blood, stool, brain, tonsil, CNS, lung cancer tissue, lymphoid and tonsil tissues.	respiratory disease (18)	55-91% (77, 118, 170)
WUPyV/ HPyV4	2007 (6)	Respiratory tract secretions	Blood, stool, brain, tonsil, CNS, CSF, lymphoid and tonsil tissues.	respiratory disease (171)	69-98% (77, 118, 170)

MCPyV/ HPyV5	2008 (7)	Skin of Merkel cell carcinoma patients	Plucked eyebrow hairs, healthy skin, liver, urine, oral samples, tonsils, gall bladder, lung, saliva, oral samples	80% of Merkel cell carcinoma (7)	58-96% (77, 170, 172-174)
HPyV6	2010 (8)	Human skin swab	Eye-brow hair, stool sample, urine, nasopharyngeal swabs	BRAF inhibitor-induced epithelial proliferations, pruritic and dyskeratotic dermatoses (48, 141)	67-98% (8, 170, 172, 174, 175)
HPyV7	2010 (8)	Human skin swab	Eye-brow hair, stool sample, urine, nasopharyngeal swabs	Pruritic and dyskeratotic dermatoses (48, 141), thymomas (139)	35-86% (8, 170, 172, 174, 175)
TSPyV/ HPyV8	2010 (9)	Skin of Trichodysplasia spinulosa immunocompromised patient	Heart, lungs, liver, small intestine, colon, allograft of kidney transplant patient, bronchus, colon tissue,	Trichodysplasia spinulosa (48)	70-84% (150, 170, 172, 174)
HPyV9	2011(10)	Serum sample of kidney transplant recipient	Skin of Merkel cell carcinoma patient, Skin of healthy people	N.A	20-70% (153, 170, 172, 174-176)

NJPyV/ HPyV13	2014 (14)	Muscle biopsy of pancreatic transplant recipient	Muscle's endothelia cells and skin	Vasculitic myopathy in pancreatic transplant recipients (14)	N.A
LIPyV	2017 (15)	Skin, eye brown hair	N.A	NA	N.A

### 3.1.4 Human polyomaviruses and associated diseases

Most immunocompetent people with a primary HPyV infection have a nonspecific influenza-like or subclinical course. However, HPyV can replicate and cause specific syndromes in the immunocompromised leading to considerable morbidities. Some HPyV-associated diseases are regularly found in specific patient populations. This suggests that viral determinants interacting within the patient or organs influence the pathological outcome. The reasons for the associations are not clearly understood (179). Different pathologies have been associated with HPyV infections. For instance, BKPyV has been associated with BKPyV-associated nephropathy, however, its association with other diseases such as cancers and autoimmune disease is still been disputed. This presents a hurdle in linking some specific pathologies to HPyVs. However, a classification of HPyVs-associated pathologies has been described (16, 161)

## **The notions of HPyVs pathologies**

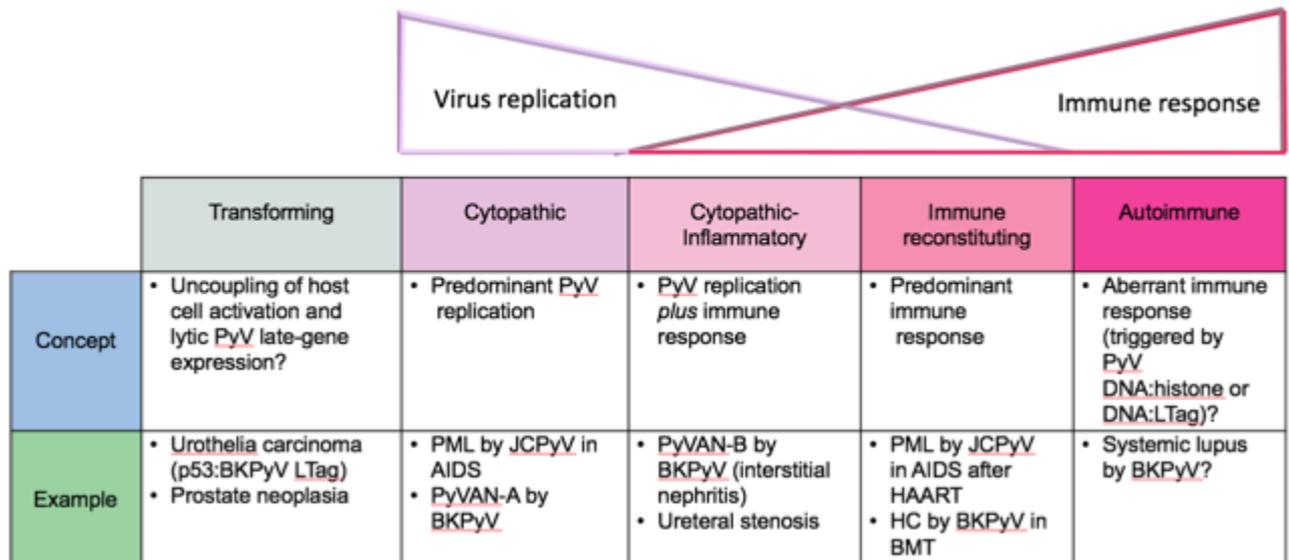

*Oncogenic HPyV pathology* is characterized by HPyV infecting host cells that allow EVGR expression, but insufficient genome replication and LVGR expression to permit rapid viral release and host cell lysis. This concept has been clearly described in the MCPyV-associated Merkel cell carcinoma, whereby truncation of the LTag and/or Vp1 and MCPyV integration into the host's genome results in the impairment of MCPyV genome replication and LVGR expression (7). BKPyV LTag uncoupling of host cell activation, LVGR expression and BKPyV release may be associated with urothelial cancers (180).

*Cytopathic HPyV pathology* is due to rapid viral replication, but with little or no inflammation, resulting to cell lysis. This is seen in JCPyV-associated PML due to an uncontrolled JCPyV replication in the brain of HIV/AIDS patients. The cytopathology is evidence by the loss of the myelin producing cells, leading to neurological deficits and disease progression.

*Cytopathic-inflammatory HPyV pathology* is characterized by high-level HPyV replication and inflammatory response as a result of cell lysis and necrotic infiltrates of lymphocytes and granulocytes. This pathological pattern is seen in BKPyV-associated PyVAN stage B in kidney allografts.

*Immune-reconstituting inflammatory syndrome (IRIS) HPyV pathology* is due to high inflammatory response to HPyV antigens, usually during a hasty recovery of the cellular immune response (161, 181). The prototypes are JCPyV-associated PML, which worsen after the commencement of highly active antiretroviral therapy (HAART) (182) or following removal of natalizumab from the plasma in multiple sclerosis patients (183).

*Autoimmune HPyV pathology* characterized by responding to 'self' which may be provoked by HPyV antigens. For instance, PyV-LTag interaction with histones and DNA may trigger antibodies against histones or DNA (184-186).

**Fig. 6:** Proposed pattern of HPyV disease during the course of viral replication and immune response adapted from (161). HAART; a colon (:) represents interaction; BMT, bone marrow transplantation; BKPyVAN-A and BKPyVAN-B, BKPyVAN patterns A and B.

BKPyV, JCPyV, MCPyV, TSPyV and HPyV7 are known to cause diseases in humans (3). Moreover, HPyV6 have been linked to certain diseases (48, 141), while other HPyVs, such as HPyV10 and NJPyV were initially detected from diseased specimens or patients (11, 156) .

### 3.1.4.1 Human polyomaviruses associated non-cancerous diseases

#### 3.1.4.1.1 BKPyV-associated diseases

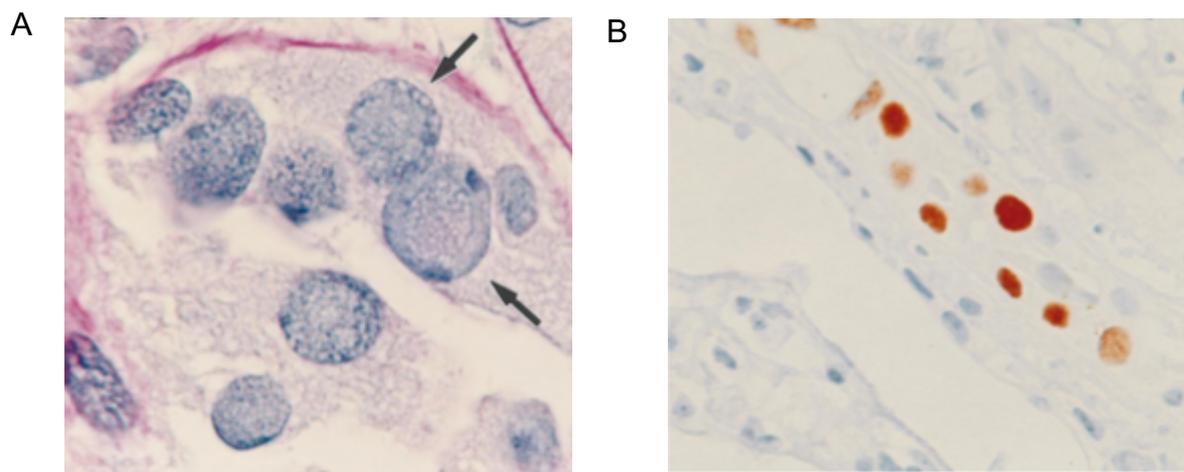

#### **Polyomavirus associated nephropathy (PyVAN)**

BKPyV was associated with PyVAN in renal transplant recipients. Approximately 1%-10% of kidney transplant recipients progress to PyVAN and up to 90% of these patients lose their allograft (187-189). PyVAN is a type of acute interstitial nephritis (190) characterized by denudation of the basement membrane (**Fig. 7A**) and necrosis of the proximal tubules due to BKPyV lytic infection and replication in kidney epithelial cells (191). The introduction of new and more potent immunosuppressive drugs suggests a relationship between immune surveillance disruption and BKPyV

reactivation (189, 192, 193). Currently, PyVAN diagnosis includes renal biopsy analyses by immunohistochemistry (IHC) (**Fig. 7B**) or histopathology to either determine cytopathic effects as a result of lysis of renal tubular epithelia cells. In addition, cytology of urine can be performed to detect decoy epithelial cells, which contain intranuclear viral inclusion bodies and PCR to detect and quantify viral load in urine or blood samples (194, 195). Urine cytology and PCR could be useful for early detection of reactivation and PyVAN (187), thus permitting faster diagnosis and intervention with a consequential increase in graft survival (196).

The risk factor for PyVAN is unclear, however combination of contributing factors from the virus, patient and graft determine the susceptibility to BKPyV. The major risk factor to PyVAN is suggested to be due to an overall degree of immunosuppression and not a particular immunosuppressive treatment (197, 198). More so, the development of PyVAN is not dependent on immunosuppression alone, since the manifestation of the disease is relatively uncommon in non-renal solid organ recipients and other immunosuppressed individuals (161). Furthermore, specific human leukocyte antigen (HLA) mismatches or donor seropositive, older age and male gender are all potential risk factors (187, 199-201).

Until now, there is no specific and effective BKPyV anti-viral treatment available. Nonetheless, decreasing immunosuppression to permit the immune system to regain control over the infection is the most common first line intervention, although may not be effective in all patients, and may expose the patient to a potential risk of acute graft rejection. Cidofovir, an antiviral nucleoside analogue, inhibits BKPyV DNA replication *in vitro* (202), but it is nephrotoxic at high doses (203). Studies revealed that at low doses and combined with the reduction of immunosuppression, Cidofovir can be effective in preventing BKPyV reactivation without causing significant nephrotoxicity (204-207). Additionally, the immunosuppressive drug leflunomide has shown some limited successes (207-209). Other antiviral treatments are fluoroquinolone antibiotics and intravenous immunoglobulin (IVIG) (197, 210-212). More detailed studies are required to evaluate the efficacies of these drugs. Lastly, rapid clearing of the viral source after nephrectomy and then re-transplantation could be another treatment approach.

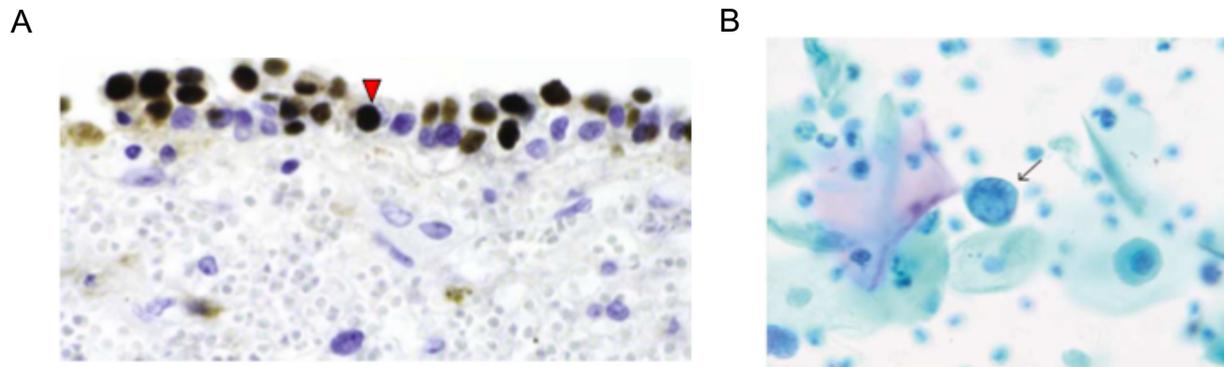

**Fig. 7:** BKPv nephropathy (213). (A) Periodic acid Schiff stained section showing tubular epithelial cells with intranuclear viral inclusion bodies (arrows). (B) Immunohistochemistry (IHC) showing a formalin fixed and paraffin embedded tissue section showing BKPv LTag staining (brown color) with SV40 LTag antibody, which cross reacts with BKPv LTag.

### **Polyomavirus-associated hemorrhagic cystitis (PyVHC)**

BKPv is also associated with PyVHC affecting 10%-25% of bone marrow transplant (BMT) patients (214). The disease is probably due to BKPv reactivation in possibly urothelial cells and renal tubular epithelial cells, resulting in high-level BKPv replication due to lack of immune surveillance. Furthermore, there is prominent denudation of the cell's basement membrane, leading to hemorrhage and inflammation (215). The disease is characterized by flank pain, dysuria with or without signs of insufficiency. Additionally, it can be associated with varying grades (grades I-IV) of hematuria (215). A classical BKPv-associated PyVHC occurs after more than 10 days post-transplantation. PyVHC is not life-threatening, but associated with significant morbidity (216-219). The most commonly applied diagnostic methods for BKPv-associated PyVHC are PCR detection of viral DNA, IHC to detect LTag expression (**Fig. 8A**) and urine cytology for the detection of decoy epithelial cells (**Fig. 8B**) (220). Other sophisticated diagnostic methods include; magnetic resonance imaging (MRI) or computer tomography (CT) to evaluate the bladder features. The bladder features in infected patients is characterized as; bladder wall thickening, increase mucosa enhancement, mural edema, small bladder capacity and

intraluminal clot (221). Like PyVAN, reduction of immunosuppression can be used as a treatment option for PyVHC, whereas exogenous BKPyV-specific T-cell application is being investigated as future therapies (214). Furthermore, antivirals including fluoroquinolone antibiotics, leflunomide, mTOR inhibitors and cidofovir are currently being evaluated for efficacy in treating BKPyV-associated diseases (222-225).

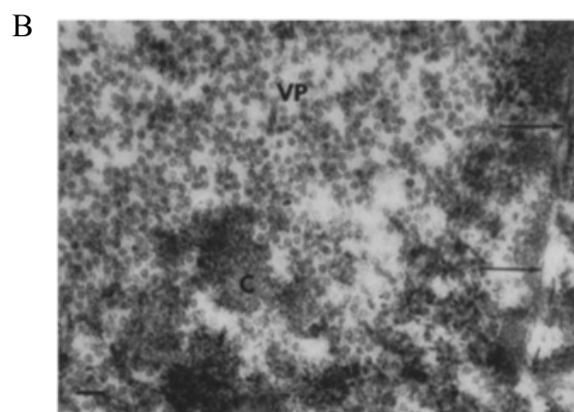

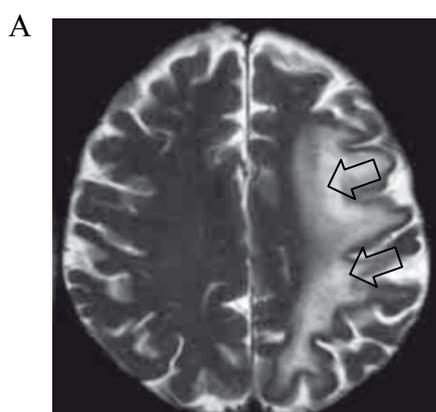

**Fig. 8:** (A) Bladder biopsy from a patient with PyVHC ([www.pathology.mc.duke.edu](http://www.pathology.mc.duke.edu)) depicting denudation and BKPyV infected cells (red arrow head) with enlarged nucleus. (B) PyVHC (220), depicting the characteristic BKPyV-infected cells with decoy cells (arrow) showing enlarged nucleus containing a large intranuclear inclusion BKPyV-associated diseases.

### **Progressive multifocal leukoencephalopathy (PML)**

JCPyV is associated with PML affecting the immunocompromised due to HIV/AIDS, cancer, transplantation and treatment of multiple sclerosis patients with Natalizumab (4, 226-228). A high activity of JCPyV IgG activity is speculative of recent infection with JCPyV, and indicative for an increased risk for PML development in AIDS patients (229). Initially, PML was considered to be a very rare disease associated with immunocompromised patients, usually those with leukemia and lymphomas (93). With the rise of the HIV/AIDS epidemic, PML resulting from JCPyV infections have drastically risen. Up to 85% of PML cases occur in AIDS patients (230, 231), since not all AIDS-affected patients or even those with very low CD4+ T cells counts come down with PML (232). However, only few sporadic PML cases develop without an underlying immunosuppression (233). In essence, PML is now regarded an AIDS-defining disease (93).

PML is clinically characterized by dementia or confusion, speech and vision impairment, varying degree of akinesia or paralysis, in concurrence with immunosuppression and lack of increase in intracranial pressure (94, 233). The progression to PML disease is rapid, with clinically-intensifying symptoms and death within 3-6 months (234), which has however, been improved with the introduction of high-active anti-retroviral therapy (HAART) (235). With respect to the cellular level, PML results as lysis of oligodendrocytes, the myelin producing cells of the brain, leading to lesion in the brain stem, cerebellum and cerebrum and especially along the white and gray matter junction (**Fig. 9A**) (236, 237). JCPyV DNA sequences have been detected in mononuclear cells and B cells within the brain (238, 239). Enlarged JCPyV Tag-expressing oligodendrocytes with crystalline arrays of viral particles (**Fig. 9B**) and nuclear inclusion bodies are other features of PML (230, 231). The high frequency of JCPyV-positive PBMCs and widely distributed brain lesions indicate that lymphocytes can serve as a reservoir and a dissemination vehicle (231, 240, 241). Whether JCPyV infection of the brain is as a result of reactivation of latent infection or *de novo* invasion of the virus is unclear (81, 242).

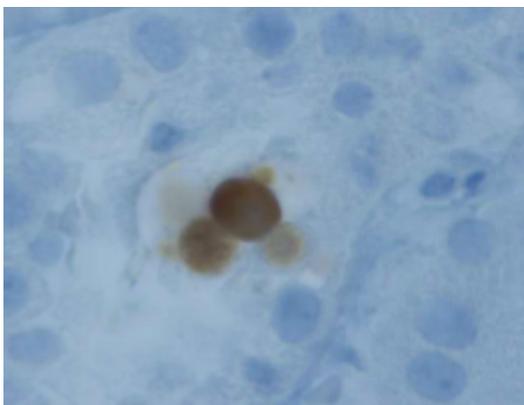

The association between PML caused by JCPyV and HIV/AIDS is not clearly understood. However, the link between these two virus-associated disease could be explained by several hypotheses (230, 243, 244). Firstly, HIV establishes a thorough immunosuppression in the host by decreasing JCPyV-specific CD4+ T-cells leading to an uncontrollable JCPyV replication. Specifically, infection of HIV may cause break down of the blood-brain barrier, permitting entry of JCPyV-harboring B cells into the brain. Furthermore, certain cytokines produced as a result of HIV infection could initiate cell signaling events that may activate the JCPyV promoter. Lastly, the HIV Tat protein may activate JCPyV promoters in vitro and increase gene expression (245). Currently, there is no specific antiviral drug to treat PML. However, clinicians now focus on immune reconstitution-based concept.

**Fig. 8:** (A) T2-weighted image of brain from patient with PML (246). The image shows multiple hyper-intense subcortical lesions in the left hemisphere (arrows). (B) Particle of JCPyV in PML lesion (226). Viral particles (VP) scattered all over major areas of the nucleoplasm. Arrows indicate nuclear membrane, while C shows nuclear chromatin.

### JCPyV-associated PyVAN

The first case of JCPyV-associated PyVAN was identified in a 15-year old with kidney transplantation (247). Kidney biopsy from the patient stained positive for LTag (**Fig. 10**) and quantitative PCR revealed high JCPyV load in the urine (247). Generally, JCPyVAN is found in approximately 1% of kidney transplant patients (248) and about 6% of HIV patients present with JCPyV replication in the kidney (249). Most patients with JCPyVAN have normal kidney function indicating that JCPyV has a more protracted course or it is apparently less aggressive compared to BKPyVAN. In addition, BKPyVAN and JCPyVAN have another difference based on the severity of the histological pattern and strong viremia associated with BKPyVAN (187). Conversely, patients shedding large amounts of JCPyV in urine or patients with parenchyma involvement have been reported to show low viremia levels. This could be due to the basic differences between the biology of JCPyV and BKPyV, which has not been resolved in detail (250, 251). With the debilitating diseases caused by JCPyV and BKPyV, there is an urgent need for the development of specific antiviral therapies.

**Fig. 10:** Kidney allograft biopsy stained positive for LTag using SV40 LTag antibody which cross reacts with JCPyV LTag.

#### 3.1.4.1.2 TSPyV-associated disease

### **Trychodysplasia spinulosa**

TSPyV was initially detected in plucked facial spines from an immunosuppressed patient with a rare skin disease called *Trichodysplasia spinulosa* (TS) (9). Development of the disease may be due to uncontrollable replication of TSPyV in the inner root sheath cells. Analysis of the lesions by EM consecutively showed regularly-spaced 38-45nm intranuclear, crystalloid-organized viral particles (144). The disease is characterized by reddened flesh-colored papules often centrally located in the face and other places of the body, usually with spines made of keratin (**Fig. 11**). TSPyV has been exclusively reported in the immunocompromised including patients with acute lymphocytic leukemia patients and solid organ transplant recipients (143, 252, 253).

TSPyV is diagnosed by histopathological examination of biopsies from lesioned skins showing enlarged hair follicles with perinuclear globules of the inner root sheath cells and evident eosinophilia. Additionally, TSPyV DNA and viral load is measured by quantitative PCR (qPCR). So far, all TS lesioned samples were positive for TSPyV with a high viral load ranging between  $10^4$ - $10^7$  genome copies per cell (9, 144). Occasionally, samples from normal skin of TS patients, plucked eyebrow hairs and skin swabs from unaffected people were TSPyV DNA-positive with a viral load of below 100 copies per cell (9, 144). There is evidence that TS is caused by TSPyV (9, 144, 252). There is no antiviral treatment available for TS. However, restoring the immune function in immunocompromised patients resulted in complete resolution of TS symptoms, although with a higher risk of graft rejection. Significant reduction of TS symptoms has been revealed in a number of TS patients treated with 1%-3% cidofovir cream (144). In addition, oral valganciclovir, a guanosine analog, showed a modest effect in some TS patients (144). The exact mechanism of action of these drugs is yet to be elucidated.

**Fig. 11:** Features of TS (9). The nose of a patient suffering from TS with numerous papules and spicules.

### **Potential diseases associated with novel HPyVs**

DNA sequences of novel HPyVs, such as HyPV6, HPyV7, HPyV9, HPyV10, HPyV12 and NJPyV, were detected in patient's samples, but not much is known with respect to their potential disease-causing role in humans (7, 10, 13, 14, 156). On the other hand MCPyV is associated with a malignant disease, MCC (reviewed below) (7). Furthermore, KIPyV and WUPyV are detected mostly in respiratory secretions from patients with respiratory diseases, but so far the association of these viruses with respiratory diseases is unclear due to co-detection with other respiratory viruses (254). Nonetheless, high-throughput sequencing of isolated RNA from a nasal swab sample from a healthy and a one-month-old boy with severe respiratory symptoms revealed transcripts of KIPyV, whereas sequences of other viruses were not detected, except of few reads from human Boca virus (18). This indicates a potential role of KIPyV in respiratory pathogenesis. On the other hand, WUPyV may also cause respiratory pathogenesis due to a reported case of WUPyV associated with bronchitis (18). HPyV6 and HPyV7 are chronically shed from the skin (8). Both viruses have been reported to be associated with dyskeratotic dermatoses and pruritic rash in immunosuppressed patients (141, 255). The patients' skin infection demonstrated brown plaques, scales and pruritus with a characteristic parakeratosis pattern (peacock plumage) (141, 255). More so, the skin biopsies presented with characteristic patterns of parakeratosis and dyskeratosis, which revealed abundance

of viral capsid, Tag, higher viral load compared to healthy skin and intact viral particles (141). HPyV6 DNA has been detected in epithelial neoplasms and the involvement of HPyV6 in the neoplasms cannot be excluded (256). Additionally, DNA of HPyV6 has been found in the CSF of an HIV/AIDS patient with PML (257) and in lymph nodes of a 51-old woman having angiolymphoid hyperplasia with kimura disease or eosinophilia (18). A hematopoietic stem cell transplant patient was diagnosed with HPyV7 viremia (18). Whether these viruses are associated with the above diseases is left to be determined. The small sample size was the major limitation to the above case reports. Probably, larger case control studies would shed more-light on disease-association of these viruses.

#### 3.1.4.2 Human polyomaviruses and cancers

Since 1953, when MPyV was demonstrated to cause tumors in newborn mice, polyomaviruses have been suspected to be an etiologic agent of cancers. The role of SV40 as an etiological agent of cancer has been debated intensively. SV40 has been reported to induce tumors in animal models, transform human cells and detected in many human tumors. Moreover, epidemiological studies failed to show significant seroconversion in the human population (258, 259). Polyomaviruses associated-oncogenesis has been solely attributed to the LTag (28, 260, 261). LTag can interact with tumor suppressor proteins pRB, p107, p130 and p53, to interfere with cellular processes such as protein degradation, transcription, DNA repair, telomerase activity, stimulates angiogenesis, apoptosis and cell migration (260, 262). Interaction with p53 and retinoblastoma proteins required the C-terminal domain and the conserved LXCXE motif. MCPyV-derived MCC cells express LTag with a C-terminal truncation of the p53 binding domain, indicating cellular transformation by MCPyV is independent on p53. (263). Moreover, the sTag may also contribute to transformation by inactivating PP2A, and thus activating anti-apoptotic and proliferating pathways, and enhancing oncogenesis (18, 260, 264). The interaction of sTag with PP2A depends on the conserved motif, CXCX<sub>2</sub>C motif. This PP2A binding motif is conserved in all polyomaviruses (177, 265, 266), but whether this motif bind PP2A in all polyomaviruses is left to be tested. One could suggest that, polyomaviruses are potential oncoviruses, since they all encode the oncogenic proteins, LTag and sTag (Fig. 3). However, avian polyomaviruses which also encode LTag and sTag do not

seem to induce tumors, which could be due to the lack of the pRB consensus binding sequence (LXCXE) found in the LTag of mammalian polyomaviruses (28, 267). Cell culture studies reported agno detection in cancers and the probable contribution of agnoprotein to tumorigenesis (261, 268).

#### 3.1.4.2.1 MCPyV-associated Merkel cell carcinoma

Out of the 14 HPyVs, MCPyV is in fact the only HPyV possibly associated with human cancer (7, 269). This virus is associated with about 80% of MCC (7, 269). MCC is a cutaneous tumor cause mostly by MCPyV. Cyril Toker was the first to described MCC in 1972 (270). He found a bluish-red or flesh-colored glassy painless nodule (**Fig. 12**) having solid trabeculae in 5 different places (lip, face, leg, forearm and buttock) of 2 elderly men, who died due to the tumors, and 3 elderly women (270). The name trabecular carcinoma of the skin was used by Toker to described these tumors, thinking that they depict an endocrine carcinoma of the sweat gland (270). MCC is classified as a group 2A carcinogenic biological agents (271). Epidemiological data revealed that this disease is affecting elderly people,

fair-skinned persons or the immunocompromised (270, 272, 273). More than 90% of MCC lesions are commonly found in sun-exposed areas, with half in the face, neck or extremities, it can also occur in perianal region, truck and genitalia although at a significantly reduced frequency (<10%) (270). The origin of primary MCC is unknown. However, the origin is thought to occur in Merkel cells, which is a type of mechanoreceptor cells found in the stratum basale in the epidermis. Excluding Merkel cells, the disease has also been suggested to originate from skin-derived precursors, and epidermal and dermal stem cells (274). Truncation of MCPyV LTag in MCPyV-positive MCC, promotes oncogenic transformation of MCPyV (275). The oncogenic potentials of MCPyV to other tumors have been extensively reviewed and documented in animal models and cell culture systems (48, 87, 91, 130, 134, 261, 263, 276-278). Moreover, the virus was not detected in squamous cell carcinoma or keratoacanthoma (279). Furthermore, MCPyV DNA was investigated in 10 small cell

lung carcinoma patients and 5 MCC patients, but was only detected in 2/5 MCC patients (280). In addition, investigation of MCPyV roles in 30 lung carcinomas, 28 prostate samples and 25 childhood brain tumors revealed no evidence of MCPyV in these cancers (129, 281). More so, MCPyV DNA was found in 10 MCCs from a study with 1241 tumors (282). However, MCPyV was not found in ovary, breast, bone, melanoma, basal cell carcinoma, soft tissue, uterine cervix and large bowel cancers (282). These suggest that MCPyV has no roles in the oncogenesis of other cancers except MCC. Furthermore, the role of MCPyV in MCC is complimented with the fact that MCC is dependent on Tag expression and patients with MCC, usually demonstrate very high levels of MCPyV antibody titers compared to the general population, suggesting that infection of MCPyV is associated with MCC.

Presently, MCC is treated by using the following therapeutic strategies; chemotherapy, radiotherapy or surgery with little effect in the setting of metastasis (283). An immunotherapy based on programmed death 1 (PD-1), revealed good response in MCC patients with and without MCPyV DNA detection (284). Lastly, probable MCC prevention could be via a MCPyV VP1-based vaccine (285). The need for specific anti-viral treatment for MCPyV is warranted.

**Fig. 12:** Merkel cell carcinoma nodule on the leg of a patient (270).

The oncogenic potentials of JCPyV, BKPyV with tumors have been extensively reviewed and documented in animal models and cell culture systems (48, 87, 91, 130, 134, 166, 261, 263, 276-278). BKPyV and JCPyV are classified as a group 2B carcinogenic biological agents with possible carcinogenicity to humans (286). The

DNA, RNA, and proteins of BKPyV and JCPyV have been detected in many tumor tissues, but also in control non-cancer tissues (87, 91, 130). Thus, the potential role of BKPyV and JCPyV in human tumors is controversial. The presence of JCPyV in colorectal and CNS tumors may increase the risk of getting the tumors, while BKPyV may be associated with prostate and renal tumors (166, 278, 287). Harald zur Hausen, suggested that JCPyV-associated colorectal tumors may be due to other polyomaviruses consumed in meat (288). Several bovine polyomaviruses related to MCPyV, HPyV6, HPyV7 and other mammalian PyVs have been identified in beef samples (289, 290). Thus far, these viruses have not been detected in human colorectal biopsies. The association of novel HPyVs with cancers have been scarcely reported with only a few cases where DNA or protein of some novel HPyVs have been detected in tumor tissues (**Table 2**). Based on the current knowledge, convincing evidence of the role of HPyVs excluding MCPyV in tumorigenesis is lacking (28, 171).

**Table 2:** Prevalence of novel HPyVs in human cancers, adapted from (28). Immunohistochemistry (IHC), fluorescence in situ hybridization (FISH).

Tumors	Number of samples	Method	Number of positive samples with HPyVs	References
Melanoma	18	PCR and IHC	HPyV6: 18, HPyV7: 17, TSPyV: 4, HPyV9: 1, HPyV10: 12	(256)
Squamous cell carcinoma (SCC)	63	PCR	HPyV6: 2, HPyV7: 1	(291)
Basal cell carcinoma	50	PCR	HPyV6: 2, HPyV7: 2	(291)
Melanoma	47	PCR	HPyV6: 2, HPyV7: 2	(291)
Basal cell carcinoma	41	PCR	HPyV6: 3	(292)
SCC	52	PCR	HPyV6: 2	(292)
SCC in situ	8	PCR	HPyV6: 1	(292)
Keratoacanthoma	42	PCR	HPyV6: 2	(292)
Actinic keratosis (AK)	31	PCR	HPyV6: 1	(292)
Breast cancer	54	PCR	HPyV6: 1, HPyV7: 1	(293)

Thymic hyperplasias	20	PCR, FISH, IHC	HPyV7: 14	(139)

### 3.1.5 Systems for HPyV propagation and infection

Bacterially expressed Vp1 pentamers represent the smallest *in vitro* model used for studying viral entry. Pentameric subunits of Vp1 have been successfully used to recapitulate early events of TSPyV and JCPyV life cycle, such as structural studies of Vp1-receptor complexes, receptor specificity, as well as intracellular trafficking routes (298-300). Vp1 of PyV can be self-assembled into VLPs (301, 302). Baculovirus and yeast expression systems have been used to produce PyV VLPs (302). These VLPs were applied in PyV seroprevalence rates screenings (19, 301, 303, 304). Pseudoviruses (PsVs) have been used for the analysis of PyV primary host cell tropism, such as viral attachment and entry. They are produced by co-transfection of mammalian cell lines such as HEK293TT (293TT) with expression vectors encoding PyV capsid proteins and vectors that encode a reporter protein, such as red fluorescent protein (RFP), green fluorescent protein (GFP) or Gaussia luciferase. This allows vivid quantification of the PsV in the target cells. Although these systems are important in revealing PyV's primary host cell tropism, the cellular factors required for viral expression and replication in the host cells cannot be analyzed using VLPs or Vp1 pentamers, since they lack the promoter of the virus which determines secondary host tropism.

So far, only BKPyV and JCPyV can be efficiently replicated in cell culture (305). Efficient propagation of archetype and rearranged variants of BKPyV and JCPyV have been conducted in the 293TT human embryonic kidney cell line (306). Viral replication, late protein expression and production of viral progeny were

demonstrated following transfection of episomal HPyVs DNA in 293TT cells. The 293TT cells carry an integrated plasmid encoding the cDNA of the SV40 LTag and a copy of the SV40 whole genome (307). The cell line constitutively expresses the SV40 LTag, which drives BKPyV and JCPyV DNA replication from their ori, but failed to significantly support replication from the ori of KIPyV, WUPyV and MCPyV. The successful replication of BKPyV and JCPyV in 293TT could be due to the fact that SV40 T antigens coding sequences have higher similarity to the BKPyV and JCPyV T antigens than the T antigens of KIPyV, WUPyV and MCPyV (306). Although large-scale propagation of BKPyV and JCPyV could be attained in these 293TT cells, this cell line is not a suitable model for the study of HPyVs` life cycle, since it has been transformed. Presently, to study BKPyV *in vitro* infection, human renal proximal tubule epithelial cells (RPTEC) are used as the state-of-the-art model. Nevertheless, the proliferative potential and the experimental design are restricted, since RPTECs could enter into replicative senescence. Rearranged BKPyV variants have been reported to replicate in a broad range of different cell lines including brain and melanoma cancer cell lines, monkey kidney cell lines (Vero and CV-1 cell lines) and human ovarian (302, 308, 309) and salivary gland cells (85, 86, 308). JCPyV has a major tropism *in vivo* for glial cells, while productively infecting oligodendrocytes and astrocytes to a lesser extent (85, 310). JCPyV infection has been mostly studied in the human fetal glial cell line, SVG which constitutively expresses SV40 LTag (311). A subpopulation of SVG p12 cells provided by ATCC has been reported by Henriksen et al., (312) to be productively infected with BKPyV (312). A subclone of the original SVG human glial cell line, SVG-A cells, which do not contain BKPyV, can be used as an alternative (312). Furthermore, efficient replication of JCPyV archetype and rearranged variants has been reported in Cos-7 which is a CV-1 cell line transformed with SV40 origin-defective mutant (311, 313).

MCPyV have been reported to be propagated in 293-4T cells, a 293TT cell line co-transfected with plasmids expressing MCPyV sTag and LTag (314). In addition, replication of MCPyV in HEK293 cells stably expressing MCPyV sTag or LTag only has also been reported (315). These results suggest that expression of specific T antigens is a limiting factor for HPyV propagation, thus specific T antigens expressing cells could be used as PyV-permissive cell culture systems for other unculturable HPyVs. Moreover, MCPyV have been replicated in cell lines not expressing MCPyV

T antigens such as, H1299 (human non-small cell lung carcinoma cell line) and PFSK-1 (neuroectodermal tumor cell line) and in HEK293 cells, but without serial infection (315, 316). This indicates that these cell lines contain the required transcription factors necessary for MCPyV replication, but lack the necessary receptor(s) and co-receptor(s) for attachment and entry.

The host cells naturally infected by HPyVs are so far unknown with the exception of MCPyV whose natural host cell has been demonstrated to be human dermal fibroblasts (317). Animal models to study HPyV infection are hampered by the narrow host range and cell specificity of HPyVs. For instance, JCPyV inoculation of hamsters or mice resulted in tumor formation, but failed to recapitulate the JCPyV demyelinating disease present in humans (318). To date, small animal models available for HPyV infection include humanized mice, xenografts, infectious mouse PyV models and transgenic mouse models (305). Available culture systems have focused mainly on the propagation of BKPyV and JCPyV with the focus on understanding the primary host cell tropism, that is receptors and co-receptors for JCPyV and BKPyV attachment and entry (319-321). Furthermore, most studies used PsVs and Vp1 pentamers, which lack important components of the viral genome. The study of viral attachment and entry receptors is important, but cellular and viral factors that interact with the HPyV-NCCRs will determine the secondary host cell tropism and potential host cells for HPyVs propagation.

The NCCR of HPyVs defines the secondary host cell tropism and is critical for all HPyVs biology (persistence, latency, reactivation). The activity of HPyV-NCCRs, especially those of novel HPyVs in cell culture is scarce, whereas that of BKPyV and JCPyV have been frequently analyzed. Examining the NCCR activity of novel HPyVs in cell culture will shed lights on HPyVs cell tropism and cell lines where they could be productively replicated. The genome of HPyVs are similar however, the HPyV-NCCRs are different with respect to length, LTag-binding sites and TFBS. NCCR rearrangement has been studied in detailed for the BKPyV and JCPyV, and less for the novel HPyVs. Therefore, understanding the effect of HPyV-NCCR rearrangement in novel HPyVs, and the detailed mechanistic role of Sp1 binding sites and LTag-binding sites in the regulation of EVGR and LVGR expression, would go a long way in deciphering possible avenues for therapeutic strategies against the growing family

of HPyVs. The role of Sp1 and LTag-binding motif on EVGR and LVGR expression were investigated in BKPyV ww as a model, which can be extrapolated to other HPyVs with similar Sp1 and LTag-binding sites organization.

## **4 AIMS OF THE THESIS**

The aims of the thesis are:

1. Compare the NCCR activity of the 13 known HPyVs in different host cell lines with respect to EVGR and LVGR expression.
2. Characterize the effect of exogenous LTag expression in HPyVs EVGR and LVGR expression.
3. Characterize the effect of different host cell lines on EVGR and LVGR expression.
4. Examine the role of predicted LTag-binding motif in the BKPyV ww NCCR with respect to EVGR and LVGR expression.

## 4.1 Hypotheses

### Question 1

Are there differences in HPyV-NCCRs activity with respect to EVGR and LVGR expression in the same host cells?

**H1:** There are differences when present in the same host cell.

**H0:** There are no differences.

### Approach

We used a bi-directional reporter vector to analyze the NCCR-driven EVGR and LVGR expression of the 13 HPyVs in HEK293 as a reference cell line.

### Interpretations

- The HPyV-NCCRs which differ in length and TFBS will sense and interpret the same host cell's transcription factors make-up to drive gene expression.
- The HPyV-NCCRs may have the same activity in the same host cells.

**Caveat:** The techniques used may not be sensitive enough to measure differences.

### Question 2

Are there differences in HPyV-NCCRs activity with respect to EVGR and LVGR expression in different host cells?

**H1:** There are differences when present in different host cells.

**H0:** There are no differences.

### Approach

We used the bidirectional reporter vector to analyze the NCCR-driven EVGR and LVGR expression of the 13 HPyVs in different cell lines.

### **Interpretations**

- The HPyV-NCCRs which differ in length and TFBS will sense and interpret different host cells' transcription factors make-up to drive gene expression.
- The HPyV-NCCRs may have the same activity in the different host cells.

**Caveat:** The techniques used may not be sensitive enough to measure differences.

### **Question 3**

Does SV40 T-antigens have effects on HPyV-NCCRs driven EVGR and LVGR expression?

**H1:** SV40 T-antigens have effects on HPyV-NCCRs driven EVGR and LVGR expression.

**H0:** SV40 T-antigens have no effect on HPyV-NCCRs driven EVGR and LVGR expression

### **Approach**

We examined the effect of T-antigens on the EVGR and LVGR expression of HPyVs in HEK293-derivative cell lines that constitutively expressing SV40 sTag and LTag.

### **Interpretations**

- The HPyV-NCCRs which differ in number and organization of LTag-binding sites will sense and response to SV40 T-antigens.
- The HPyV-NCCRs may not response to SV40 T-antigens.

**Caveat:** Our techniques used may not be sensitive enough to measure HPyV-NCCRs' response to SV40 T-antigens.

### **Question 4**

Does SV40 T-antigens have different effects on HPyV-NCCRs driven EVGR and LVGR expression?

**H1:** SV40 T-antigens have different effects on HPyV-NCCRs driven EVGR and LVGR expression.

**H0:** SV40 T-antigens have the same effect on HPyV-NCCRs driven EVGR and LVGR expression.

### **Approach**

We examined the effect of T-antigens on the EVGR and LVGR expression of HPyVs in HEK293-derivative cell lines that constitutively expressing SV40 sTag and LTag.

### **Interpretations**

- The HPyV-NCCRs which differ in number and organization of LTag-binding sites will sense and response to SV40 T-antigens differently.
- The HPyV-NCCRs may response the same to SV40 T-antigens.

**Caveat:** Our techniques used may not be sensitive enough to measure the difference in HPyV-NCCRs' response to SV40 T-antigens.

### **Question 5**

Does mutageneses of LTag-binding sites of BKPyV-NCCR have an effect on EVGR and LVGR expression in HEK293 cells and HEK293-derivative cell lines that constitutively expressing SV40 LTag in different amounts?

**H1:** There is an effect on EVGR and LVGR expression.

**H0:** There is no effect on EVGR and LVGR expression.

### **Approach**

We used the bi-directional reporter to compare the BKPyV ww NCCR-driven EVGR and LVGR expression to designed BKPyV ww NCCR defective in one or more LTag-binding sites.

### **Interpretations**

- The number and position of LTag-binding sites will affect the NCCR-driven EVGR and LVGR expression.
- The number and position of LTag-binding sites has no role with respect to EVGR and LVGR expression

**Caveat:** Our techniques might not be sensitive to measure the EVGR and LVGR expression of the different LTag-binding site mutants.

## 4.2 Rationales

Increasingly, the HPyVs are considered to be emerging opportunistic viruses. Very little is known about the basic biology of these viruses, especially the newly discovered HPyVs. Information on the route of transmission, associated diseases, medical treatment, life cycle, viral gene regulation, cell tropism and replication in cell culture are lacking. Furthermore, the NCCR activity which can be used as an indicator of HPyV cell tropism and replication in cell culture is lacking for the newly discovered HPyVs. Propagation of these viruses in cell culture is scarce; only BKPyV and JCPyV can be efficiently replicated in cell culture. Nonetheless, many cell culture studies have focused on the mechanisms of HPyV primary host cell entry by using Vp1 pentamers, VLPs and pseudoviruses, which do not include all aspects of the viral replication cycle. Although primary host cell tropism is important, cellular factors or early viral proteins that interact with the NCCR will affect viral expression and replication, thus determining the secondary host cell tropism. The NCCR of HPyVs functions as a bi-directional promoter, regulating the EVGR and LVGR expression and determining the permissiveness of HPyVs in their host cells. Analyzing NCCR activity of the 13 HPyVs, the roles of LTag and Sp1 binding motif with respect to EVGR and LVGR expression, would throw lights on the basic biological aspects of HPyVs, help in the development of cell culture systems for propagating HPyVs, identification of cell tropism and open avenues for new therapeutic approaches for eliminating these viruses, especially in the context of immunosuppression.

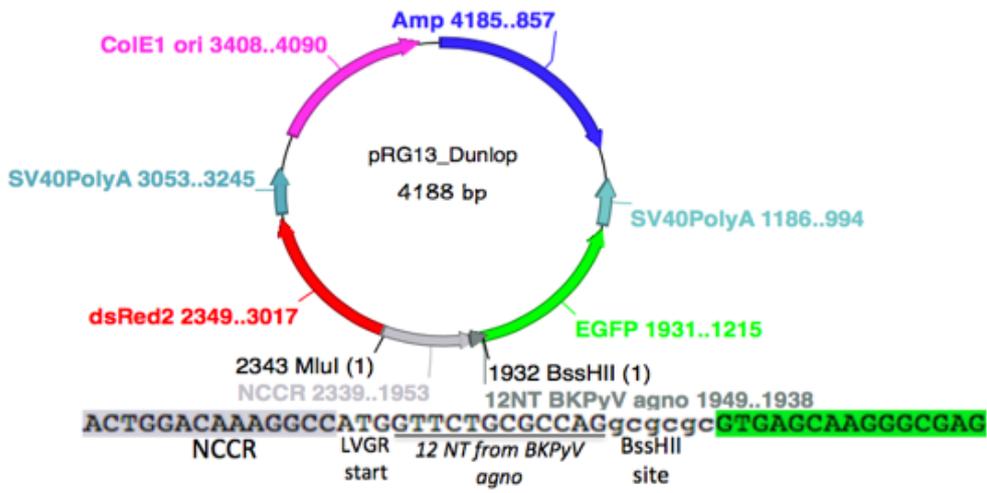

## 5 RESULTS

### 5.1 Designing a smaller bi-directional reporter vector lacking some sequences compared to the previous pHRG reporter vector

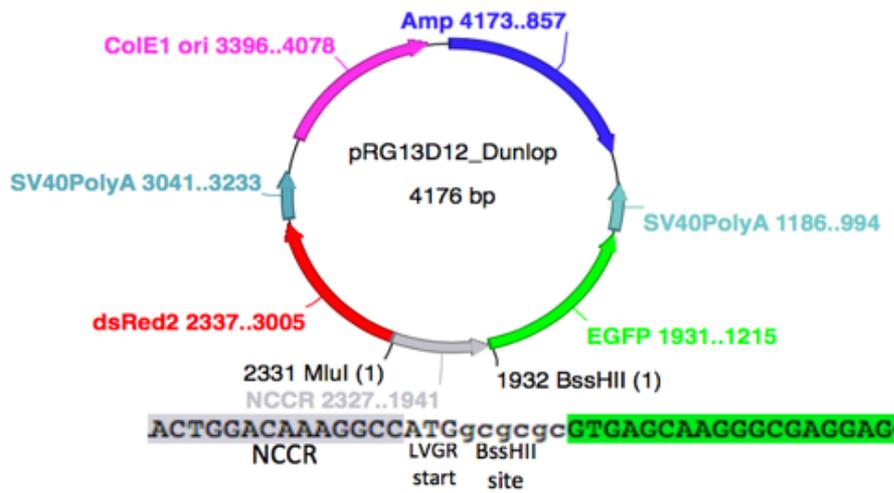

Transfection of large plasmids has been reported to have lower efficiency than small ones in human cell lines. We designed a new-smaller bi-directional reporter pRG13 recapitulating the HPyV genome (**Fig. 1A**) based on the pHRG reporter described in Gosert et al. (25). Compared to pHRG (25), the reporter lacks the beta globulin polyadenylation signal, Hygromycin gene and an SV40 early promoter, which could compete with the NCCR. The late leader sequence encoding the agno protein of JCPyV has been reported to contain potential regulatory elements. Deletion or mutagenesis analyses of this sequence significantly decreased EVGR expression and thus viral replication (322). Furthermore, clinical BKPyV variants with agno gene deletion have been identified to be non-functional (323). PhRG and the newly designed pRG13 contain a 12-nucleotide sequence of BKPyV ww agno gene (nucleotides number 4-15) immediately after the NCCR and the start codon of EGFP (**Fig. 1A**). We deleted the 12-nucleotide sequence in pRG13 (BKPyV-Dunlop) (**Fig. 1B**) and pHRG (BKPyV-Dunlop) and transfected HEK293 cells. Two days post-transfection, we quantified the EVGR and LVGR expression by flow cytometry and calculated the mean fluorescence intensity (MFI) of EVGR (red) and LVGR (green) expression (**Material and Methods in section 5.2**). Surprisingly, both reporter vectors showed reduction in EVGR expression in favor of LVGR expression of more than 5-fold compared to the respective undeleted ones (**Fig. 1C, D**). We suspected the 12-nucleotide sequence harbored vital regulatory TFBS. To visualize this, we used the MatInspector tool (324) to search the 12-nucleotide sequence for the presence of TFBS. We identified putative TFBS including one for nuclear factor 1 (NF1), which we called NF1-7 representing the 7<sup>th</sup> NF1 binding site with respect to the six NF1 bindings sites in the BKPyV ww NCCR (**Fig. 2A**). Since many studies have reported NF1 to be an important regulator of viral expression (325, 326), we made pHRG (BKPyV-DUN) constructs with mutations within the 12-nucleotides sequence that would affect the core binding site of NF1 (NF1-7\_mut1, NF1-7\_mut2

and NF1-7\_mut4) and another that would not affect the core NF1 binding site (NF1-7\_mut3) (**Fig. 2A**). The core NF1 binding site is shown on the right of Fig. 3A. The result revealed, that mutagenesis of the predicted NF1-7 site decreased EVGR expression to ~30%, while the LVGR expression increased ~2.6-fold, but not up to the levels of the deletion mutant (**Fig. 2B, C**). This indicates that other factors within the deletion may be involved in the regulation of EVGR and LVGR expression. On the other hand, mutation, which did not affect NF1 binding, had little or no effect on EVGR or LVGR expression. This result suggested that the immediate BKPyV agno coding sequence (nucleotides 4-15) contained an NF1 binding site, which may cooperate with other factors to regulate EVGR and LVGR expression of BKPyV. Since the 12-nucleotide sequence could have a regulatory function and novel HPyVs do not encode agno, we analyzed the HPyVs-NCCR activity in a bi-directional reporter pRG13D12 (D12 indicates pRG13 lacking the 12-nucleotide sequence) in section 5.2.

**Fig. 2:** (A) The 12-nucleotide sequence (shaded blue, indicating nf1 binding) of BKPyV ww agno in the phRG reporter, adjacent is the BssHII site (shaded orange). The bases in red color within the 12-nucleotide sequence are the different mutation substituted within the core NF1 binding sites which can potentially affect nf1 binding (nf1-7\_mut1, \_mut2, and \_mut4) or in the non-core binding sites which may not affect nf1 binding (nf1-7\_mut 3). The alphabets depict the single amino acid codes. On the right of Fig2A is the sequence logo of NF1 core binding site shown in capital letters. (B) Analysis of flow cytometry of BKPyV Dunlop NCCR cloned in phRGD12

reporter vector (12-nucleotide sequence deleted as explained above) and also cloned in pHRG reporter vector including nf1 NCCR mutants. Transfection was done in HEK293 cells. x-axis, EGFP fluorescence, y-axis, dsRed2 fluorescence, 10,000 mock transfected cells were gated for the live gate while 5,000 transfected cells were gated for the P3 (Q<sub>1</sub>, Q<sub>2</sub> and Q<sub>4</sub>) gate. Q<sub>1</sub>, Q<sub>4</sub> and Q<sub>2</sub> depict cells expressing red, green and both, respectively. Ex. excitation wavelength, Em, emission wavelength. **(C)** Summary plot, red bars, sum of red cells (Q<sub>1</sub>+Q<sub>2</sub>); green bars, sum of green cells (Q<sub>2</sub>+Q<sub>4</sub>); yellow bars double-positive cells (Q<sub>2</sub>). **(D)** Plot of weighted MFI was calculated for each measurement (see formulas in Materials and Methods).

This manuscript is under review.

## **5.2 Novel human polyomavirus non-coding control regions differ in bi-directional gene expression according to host cell, large T antigen expression and clinically occurring rearrangements**

There is a rapidly expanding family of HPyVs with 13 HPyVs identified so far, suggesting many more would be identified. The question of HPyVs' host cell tropism, replication in cell cultures, route of transmission and associated diseases is raised. HPyVs widely infect humans and show differences in their associated diseases and tissue tropisms. Many aspects of the basic biology of these viruses, especially those of the novel HPyVs, are unknown. Presently, cell lines for propagating the novel HPyVs are lacking, thus hindering basic research on these emerging viruses. Currently, only BKPyV and JCPyV can be efficiently propagated in cell culture (305, 306). Attempts to efficiently propagate MCPyV in cell culture were futile, as only low-level virion production by transfection/infection of HEK293 cells was achieved with no serial transmission (17). To understand the primary host cell tropism, many studies have looked at the entry mechanisms of HPyVs into host cells by using VLPs, Vp1 pentamers and pseudoviruses (327). The NCCR activity which can be used as an indicator of HPyV secondary host cell tropism and replication in cell culture, has not been thoroughly investigated, especially for the recently discovered HPyVs. The fundamental feature of the genome organization is similar among the family of HPyVs. However, the NCCR sequences differ among HPyVs with respect to length,

LTag-binding sites and TFBS, which may have influence on host cell tropism and viral replication. We hypothesized that the HPyVs will demonstrate different activity in cells derived from the same or different tissues. We designed a smaller bi-directional reporter vector based on the one described in Gosert et al., (25). The bi-directional reporter vector contains the red fluorescence protein (dsRed2), which serves as a marker of EVGR, and the green fluorescence protein (EGFP) as a marker of LVGR expression. We tested the NCCR activity of the 13 HPyVs including (rr)-NCCRs from HPyV7 and HPyV9 from patients and MCPyV point mutant from MCC using HEK293 as our basic cell line. The early viral proteins (sTag and LTag) are involved in the regulation of EVGR and LVGR expression and viral genome replication. To characterize the effect of Tags on EVGR and LVGR expression, we analyzed our HPyV-NCCR reporter constructs in HEK293T cells constitutively expressing SV40 Tags and HEK293MCT constitutively expressing MCPyV Tags. Next, to get an indication of secondary host cell tropism, we investigated the NCCR activity of the 13 HPyVs in different cell lines originating from kidney, skin, lung, cervix, brain and colon. Quantification of EVGR and LVGR expression was performed by fluorescence microscopy and flow cytometry.

37 **ABSTRACT (244 WORDS)**

38 Human polyomavirus (HPyV) DNA genomes contain three regions denoted early viral gene region  
39 (EVGR) encoding the regulatory T-antigens, late viral gene region (LVGR) encoding the structural  
40 capsid proteins Vp1-3, and non-coding control region (NCCR). The NCCR harbours the origin of  
41 viral genome replication and bi-directional promoter/enhancer functions governing EVGR- and  
42 LVGR-expression from opposite DNA strands. Despite principle similarities, HPyV-NCCRs differ  
43 in length, sequence, and architecture. To functionally compare HPyV-NCCRs, sequences from  
44 human isolates were inserted into a bi-directional reporter vector using dsRed2 for EVGR- and  
45 EGFP for LVGR-expression, respectively. Transfecting HPyV-NCCR reporter vector into human  
46 embryonic kidney (HEK)-293 cells and flow cytometry results normalized to archetype BkPyV-  
47 NCCR revealed a hierarchy of EVGR-expression levels with MCPyV-, HPyV12-, and STLPyV-  
48 NCCRs conferring stronger, and HPyV6-, HPyV9-, and HPyV10-NCCRs weaker levels, while  
49 LVGR-expression showed less variability. Transfection of HEK293T cells expressing the SV40-  
50 large T-antigen (LTag) increased EVGR-expression compared to HEK293 levels for most HPyV-  
51 NCCRs, which correlated with the number of LTag-binding sites (Spearman  $r$  0.625;  $p < 0.05$ ). LTag  
52 activation was specifically confirmed for 2 different MCPyV-NCCRs in 293MCT cells expressing  
53 the cognate MCPyV-LTag. Clinically occurring NCCR-sequence rearrangements of HPyV7-PITT1  
54 and -2, and HPyV9-UF1 were found to increase EVGR-expression compared to the respective  
55 HPyV archetype, but which was partly host cell type-specific. HPyV-NCCR expression in different  
56 cell lines derived from skin (A375), cervix (HeLaNT), lung (A549), brain (Hs683), and colon  
57 (SW480) demonstrated that host cell properties significantly modulate baseline the HPyV-NCCR  
58 activity.

59

60 **AUTHOR'S SUMMARY (140 WORDS)**

61 HPyV-NCCRs integrate essential viral functions with respect to host cell specificity, persistence,  
62 viral replication, and disease. Here, we show that HPyV-NCCRs differ not only in sequence length,

63 number and position of LTag- and common transcription factor-binding sites, but also confer  
64 differences in bi-directional viral gene expression. Importantly, EVGR-reporter expression was  
65 significantly modulated by LTag-expression and by host cell properties. For the first time, clinical  
66 sequence variants of HPyV7- and HPyV9-NCCRs containing deletions and insertions were  
67 associated with increased EVGR-expression similar to BKPyV- and JCPyV-rearrangements  
68 emphasizing that HPyV-NCCR sequences are major determinants not only of host cell tropism,  
69 but also pathogenicity. These results are essential for understanding secondary HPyV cell tropism  
70 beyond HPyV surface receptors, for identifying key viral and host factors shaping the viral life  
71 cycle, and for developing pre-clinical models of HPyV persistence, replication, and disease, to  
72 identify suitable antiviral targets.

73 **INTRODUCTION**

74 Polyomaviruses (PyVs) belong to the *Polyomaviridae* family, which is characterized by a restricted  
75 host range they can productively infect (1). PyV virions are non-enveloped icosahedral particles  
76 of approximately 45 nm diameter containing a circular, double-stranded DNA genome of about 5  
77 kb (1, 2). More than 70 PyVs have been identified to date, and at least 13 are known as human  
78 polyomaviruses (HPyVs) (3). In 1971, isolation of BKPyV and JCPyV by cell culture was reported  
79 from urine of a kidney transplant patient and from brain tissue of a patient with progressive  
80 multifocal leukoencephalopathy (PML), respectively (4, 5). In the past decade, molecular  
81 techniques have led to the discovery of 11 novel HPyVs called Karolinska institute polyomavirus  
82 (KIPyV) (6), Washington University polyomavirus (WUPyV) (7), Merkel cell polyomavirus (MCPyV)  
83 (8), human polyomavirus 6 (HPyV6) (9), human polyomavirus 7 (HPyV7) (9), *Trichodysplasia*  
84 *spinulosa* polyomavirus (TSPyV) (10), human polyomavirus 9 (HPyV9) (11), human polyomavirus  
85 10 (HPyV10) (12), St.Louis polyomavirus (STLPyV) (13), human polyomavirus 12 (HPyV12) (14),  
86 and New Jersey polyomavirus (NJPyV) (15). While this work was in progress, Lyon IARC PyV  
87 (LIPyV) has been described, awaiting further confirmation as HPyV (16).

88 The molecular detection of HPyV genomes was complemented by serological evidence of  
89 infection detecting HPyV capsid-specific antibodies. The results indicated that HPyV infections  
90 frequently occur during childhood reaching high seroprevalence rates of 60% - 90% in the general  
91 adult population, with average co-exposure rates of 7 HPyVs (17-19). Despite this high rate,  
92 clinical symptoms or signs of HPyV infection have not been identified. In fact, only 5 HPyVs have  
93 been consistently linked to disease: BKPyV to nephropathy and hemorrhagic cystitis (20), JCPyV  
94 to PML and nephropathy (21), MCPyV to Merkel cell carcinoma (8); TSPyV to *trichodysplasia*  
95 *spinulosa* (10), and HPyV7 to pruritic hyperproliferative keratinopathy (22), whereby disease  
96 occurs almost exclusively in inherited, acquired, or therapeutic immunodeficiency states including  
97 transplantation, HIV-AIDS, autoimmune disease, and cancer/chemotherapy (3, 23). Evidence of  
98 HPyV disease is emerging for KIPyV (24), WUPyV (25, 26), HPyV6 (27, 28), HPyV10 (12) and

99 NJPyV-2013 (15) due to dedicated studies correlating cytopathic alterations and virus infection by  
100 specific immunohistochemistry.

101 Despite this plethora of different HPyVs, the genome can be divided into three common regions:  
102 Early viral gene region (EVGR) encoding the regulatory large T antigen (LTag) and small T antigen  
103 (sTag) as well as various spliced derivatives; late viral gene region (LVGR) encoding the structural  
104 Vp capsid proteins; non-coding control region (NCCR) harbouring the origin of viral replication and  
105 bi-directional promoter/enhancer functions governing EVGR and LVGR-expression from opposite  
106 DNA strands through numerous transcription factor binding sites (TFBS) (1, 3, 29). Of note,  
107 rearrangements of the archetype NCCR of BKPyV and JCPyV have been identified in patients  
108 with nephropathy (30) and PML (21, 31), respectively, and were shown to confer higher EVGR-  
109 expression, augmented viral replication capacity, and increased cytopathology compared to their  
110 archetype counterparts (30, 32, 33). However, systematic functional comparisons of novel HPyV  
111 replication and their rearranged variants, have not been reported so far. In fact, cell culture  
112 propagation of the novel HPyVs has been difficult, which severely limits studies of viral replication  
113 and antiviral targets. However, HPyV – host cell interactions have been studied at the level of  
114 viral capsid – receptors defining primary HPyV cell tropism and entry have been characterized (29,  
115 34-36). Yet, the NCCR defines a second level of host cell tropism intranuclearly, which is critical  
116 for coordinating and directing essential steps of HPyVs biology from latency/persistence to  
117 progression through the viral life cycle (37). To experimentally overcome the NCCR bottle neck,  
118 researchers have resorted to viral recombinants carrying genomes with hybrid NCCRs e.g.  
119 between SV40 and JCPyV (38, 39) or provided SV40 EVGR proteins like the LTag *in trans* (40-  
120 43). To understand the role of TFBS in archetype and rearranged HPyV-NCCRs, we have chosen  
121 archetype BKPyV-NCCR as a model, and introduced inactivating point mutations in 28 common  
122 TFBS (44). We identified three phenotypic groups of i) strong, ii) intermediate, or iii) low EVGR-  
123 expression and corresponding viral replication capacity (44). Interestingly, a prominent role  
124 emerged for binding sites for rather common host cell factors such as Sp1, Ets1, and NF1 (44).

125 However, as revealed for two key Sp1 sites in the EVGR and the LVGR promoter, respectively,  
126 their location, directionality, and affinity resulted in graded activation of EVGR-expression at the  
127 expense of LVGR-expression (45). When examining the NCCRs of the HPyVs, we found  
128 differences not only in NCCR length, but also in number and composition of common TFBS and  
129 LTag binding sites. We therefore hypothesized that these NCCR differences give rise to different  
130 bi-directional EVGR- and LVGR-expression patterns. To this end, our results indicate the  
131 presence of a hierarchy of HPyV EVGR-expression, which is modulated by host cell, LTag  
132 expression, and clinically occurring NCCR rearrangements.

133 **RESULTS**

134 **HPyV-NCCRs confer different strength of EVGR-expression**

135 Given the prominent role of Sp1, Ets1, NF1, and LTag in the archetype BkPyV-NCCR (44, 45),  
136 we compared the archetype NCCRs of BkPyV, JcPyV and 11 novel HPyVs and found not only  
137 differences in overall length, but also in number and composition of these binding sites (46) (**Fig.1**).  
138 LTag-binding sites were predicted in all HPyV-NCCRs and preferentially located in the EVGR-  
139 promoter region with an average of 5 ranging from 1 and 2 for HPyV6- and HPyV7- to 10 and 12  
140 for TSPyV- and MCPyV-NCCRs. NF1-sites were preferentially predicted in the LVGR, but some  
141 HPyV-NCCRs had one and less (MCPyV, HPyV6, HPyV7, HPyV9). Sp1-, Ets1-, and Spi-B-sites  
142 were found in all HPyV-NCCRs and often in clusters (**Fig.1**).

143 We therefore hypothesized that these differences in NCCR result in different bi-directional EVGR-  
144 and LVGR-expression. To test this hypothesis, we compared 13 archetype HPyV-NCCRs using a  
145 novel bi-fluorescent reporter vector pRG13D12 recapitulating the PyV genome organization  
146 regarding bi-directional EVGR and LVGR (**Fig.2A**). To validate its suitability (**Fig. 2B**), NCCRs of  
147 the well-characterized archetype BkPyV(ww) and the rearranged BkPyV-Dunlop strain were  
148 inserted in forward orientation or the BkPyV-Dunlop strain NCCR was inserted in reversed  
149 orientation, the resulting reporter constructs transfected into HEK293 cells, and analysed by flow  
150 cytometry at 48 hours post transfection (hpt). Indeed, the rearranged BkPyV-NCCR(DUN)  
151 conferred significantly stronger EVGR-expression (red) compared to archetype BkPyV(ww)  
152 NCCR (**Fig. 2C**) and the BkPyV-Dunlop NCCR cloned in reversed orientation displayed opposite  
153 expression compared to the BkPyV-Dunlop cloned in forward orientation, in line with previous  
154 results (30, 44). Quantification of the number of fluorescent cells (**Fig. 2D**) and the mean  
155 fluorescent intensity (MFI) indicated that the simplified reporter vector pRG13D12 captured these  
156 differences (**Fig. 2E**), hence being suitable for a principle comparative analysis of HPyV-NCCRs.

157

158 To that end, 13 archetype HPyV-NCCR sequences were inserted into pRG13D12, verified by

159 sequencing, and transfected into human embryonic kidney HEK293 cells. EVGR- and LVGR-  
160 expression were quantified by flow cytometry and the results normalized to the archetype BkPyV-  
161 NCCR(ww). The results demonstrated that EVGR-expression in HEK293 cells varied over more  
162 than 3 orders of magnitude (**Fig. 3A**). MCPyV- and HPyV12-NCCR were located at the upper end  
163 of the EVGR-responses, whereas HPyV6- and HPyV9-NCCRs were found at the lower end. The  
164 corresponding LVGR-expression also showed some variability, but tended to be within the same  
165 order of magnitude (**Fig. 3A**). The results indicated that HPyV-NCCRs give rise to a hierarchy of  
166 EVGR-expression levels in HEK293, which were higher, similar, and lower than the corresponding  
167 archetype BkPyV-NCCR activity in HEK293.

168

#### 169 **Large T-antigen activates HPyV NCCR-controlled EVGR-expression**

170 Since LTag is a major regulatory protein encoded in the EVGR, exerting key functions on viral  
171 replication and gene expression, part of which are mediated directly through LTag-binding sites  
172 (**Fig.1**, red triangles), it was of interest to investigate the effect of LTag on HPyV-NCCR reporter  
173 expression. To ensure comparable conditions for all 13 HPyV-NCCRs, the well-characterized  
174 HEK293 derivative 293T cells were chosen, which constitutively express SV40-LTag (45).  
175 Transfection and flow cytometry analysis 48 hpt showed that the overall hierarchy of EVGR-  
176 expression was only little changed, whereby MCPyV and HPyV12 were in the higher group, and  
177 HPyV6 and HPyV7 remained in the lower group (**Fig. 3B**). However, JCPyV EVGR-expression  
178 appeared to be most responsive to SV40-LTag and now located among those HPyVs conferring  
179 equal or higher NCCR-driven EVGR-expression than BkPyV. Compared to HEK293, EVGR-  
180 expression in HEK293T cells increased more than 10-fold for some HPyV-NCCRs including  
181 BkPyV, whereas only little change was observed for HPyV6. LVGR-expression also increased  
182 but to lesser extent (**Fig.3C**). Thus, most, but not all HPyV-NCCR were able to respond to SV40-  
183 LTag *in trans* with significantly increased EVGR-expression.

184

185 As noted above, the LTag-binding sites differed in number and location among the different HPyV-  
186 NCCRs (**Fig.1**). HPyV6- and HPyV7-NCCR contained the lowest number (1 and 2 sites,  
187 respectively) of LTag-binding sites, while MCPyV-NCCR harbours the highest number (12 sites)  
188 of LTag binding sites, which appeared to partly correlate with the EVGR-expression levels in  
189 HEK293T cells (Spearman correlation, Spearman  $r$  0.625;  $p < 0.05$ ; **Fig.3D**). Of note, HPyV12 and  
190 TSPyV deviated by showing significantly higher and lower levels, respectively. Together, the data  
191 indicated that SV40-LTag *in trans* provided an important stimulus to the basal EVGR-expression  
192 of most HPyV-EVGR, but also suggested that other factors related to the primary HPyV-NCCR  
193 sequence mattered.

194

#### 195 **Autologous MCPyV-LTag increases MCPyV-NCCR EVGR-expression**

196 Although SV40-LTag has considerable homology to the LTag encoded in HPyV genomes (29,  
197 37), differences in amino acids and in the host range domain has been noted, which can be  
198 grouped in one of seven clades (47). We wondered whether or not the known strong and  
199 pleiotropic action of SV40-LTag in 293T cells could be an appropriate indicator and surrogate of  
200 the cognate viral LTag. We addressed this question for MCPyV by examining two MCPyV-NCCR  
201 reporter constructs in 293MCT (48) expressing the cognate MCPyV-LTag (**Fig.4A**). One NCCR  
202 had been detected in healthy skin and was tested above (MCPyV-R17b) (9), while the other one  
203 had been detected in a Merkel cell carcinoma carrying 1 C->G substitution and 1 'A' base deletion  
204 in an A-rich sequence stretch (MCPyV-MCVw156) (49). The results demonstrated increased  
205 EVGR-expression from two different MCPyV-NCCRs in 293MCT cells, thus independently  
206 supporting the results obtained with SV40-LTag in 293T cells (**Fig. 4BCD**).

207

#### 208 **Rearranged NCCR patient variants increase EVGR-expression**

209 Clinical NCCR sequence variants of the novel HPyVs have been described (22, 28, 50), but their  
210 effect on bi-directional EVGR- and LVGR-expression has not been compared with the respective

211 archetype NCCRs. We therefore examined the rearranged HPyV7-NCCR variants -PITT1 and -  
212 PITT2 (**Fig.5A**) detected in two lung transplant patients with hyper-proliferative keratinopathy (22).  
213 The data demonstrated a significant increase of HPyV7-PITT1 and -PITT2-EVGR-expression in  
214 the skin cell line SW480, while only a trend to higher levels was observed in HEK293 (**Fig.5A**).  
215 For the rearranged HPyV9-UF1 (**Fig.5B**), a significant increase of EVGR-expression over  
216 archetype HPyV9-NCCR activity was observed in both, HEK293 and in the lung cancer line A549,  
217 whereas little change in LVGR-expression was noted (**Fig.5B**). These results indicated that  
218 naturally occurring NCCR rearrangements of the novel HPyV7 and -9 are able to confer increased  
219 EVGR-expression, but that this effect also depended on the host cell context.

220

#### 221 **Role of host cells for bi-directional NCCR-expression**

222 Given the role of the host cell context suggested above, we analysed the NCCR-driven EVGR-  
223 and LVGR-expression of the 13 HPyV-NCCR reporter constructs in different cell lines derived  
224 from skin, lung, cervix, brain and colon (**Table 1, Table 2**). Indeed, HPyV-NCCR showed  
225 differences in EVGR- and LVGR-expression according to the host cell lines tested (**Table 1**). Thus,  
226 MCPyV demonstrated the strongest EVGR-expression in the skin-derived A375 cells, and  
227 intermediate levels in the epithelial cell lines derived from kidney and colon, whereas cervix, lung,  
228 and brain cell lines showed rather low EVGR-expression. HPyV12-NCCR conferred stronger  
229 expression in brain and colon, followed by lung, cervix and skin cell lines, while remaining relatively  
230 low in kidney-derived cell lines. JCPyV-NCCR EVGR-expression was highest in brain-derived  
231 cells, whereas BKPyV-NCCR showed highest EVGR-expression in kidney, followed by lung- and  
232 colon-derived cell lines. KIPyV-NCCR driven EVGR-expression was highest in cervix and brain  
233 followed by lung, while WUPyV-NCCR was highest in the colon-derived cell line (**Table 1**).  
234 Complementary LVGR-expression levels were observed for these HPyV-NCCRs, some of which  
235 decreased as the EVGR-expression levels were higher. Taken together, the data demonstrate  
236 that the bi-directional activity of a given HPyV can substantially differ in different host cells.

237 **DISCUSSION**

238 The results of the present study demonstrate that HPyV-NCCRs not only differ in sequence length,  
239 number and position of binding sites for LTag and rather common factors like Sp1, NF1, and Ets1,  
240 but also confer significant differences in viral gene expression. This difference in basal EVGR  
241 expression is most impressively captured in HEK293 cells by the high levels seen for MCPyV- and  
242 HPyV12-NCCRs at the upper end, and which range to the 2 orders of magnitude lower levels seen  
243 for HPyV6-NCCRs. LVGR-expression was generally strong, but varied less among the different  
244 archetype HPyV-NCCRs as described for the archetype BKPvV-NCCR(ww) (30, 32).

245 The functionality of the bi-directional MPyV-NCCR reporter activity was further addressed by  
246 providing the SV40 homolog of the EVGR-encoded LTag *in trans* (29, 51) in 293T cells, which  
247 showed increased EVGR-expression levels for practically all HPyV-NCCRs. This indicates that  
248 the reporter construct recapitulated an essential NCCR response described in detail for the viral  
249 life cycle of polyomavirus representatives such as SV40 or BKPvV (1, 29, 30, 44). LVGR-  
250 expression was also increased, although to a lesser extent in line with the bi-directional balance  
251 of EVGR- versus LVGR-expression (45). Although SV40-LTag has been recognized and exploited  
252 as a strong pleiotropic activator of HPyV gene expression, the autologous LTag of some HPyVs  
253 might confer only selective responses as reported for the effect of JCPyV-LTag on its cognate  
254 JCPyV-NCCR that are not necessarily captured by the SV40- or BKPvV-NCCR (52). Since we  
255 could not assess the specific impact of each of the 13 HPyV-LTag orthologues on their respective  
256 NCCR, our observations were supported by the impact of MCPyV-LTag in 293MCT (48)  
257 demonstrating a similar activation of EVGR-expression for two different MCPyV-NCCRs, one from  
258 a healthy control and one from a Merkel cell carcinoma bearing a G-to-C point mutation.

259 The role of the HPyV-NCCR sequences as differential determinants of EVGR- and LVGR-  
260 expression was further strengthened by the correlation of the number of LTag-binding sites and  
261 the level of EVGR expression in 293T cells. However, there were also two notable exceptions

262 such as HPyV12-NCCR, which showed much higher EVGR-expression than predicted from the  
263 number of LTag-binding sites, whereas the opposite was true for the TSPyV-NCCR EVGR-  
264 response. This suggested that other regulatory elements were critical in determining the EVGR-  
265 response. In this context, the higher expression of rearranged BKPyV(DUN)-NCCR compared to  
266 the archetype BKPyV<sub>vw</sub> should be noted, which carries a deletion of one LTag site together with  
267 the high-affinity *SP1-4* site in the LVGR-promoter (45). Deletions and insertions in HPyV7-PITT1,  
268 HPyV-PITT2, and HPyV9-UF1 were also associated with increased EVGR-expression despite  
269 rather small alterations of the primary sequence. Thus, HPyV-NCCR sequences are key  
270 determinants of EVGR-activity and suggests for the first time that the pathogenicity of the  
271 respective variants would likely be increased in susceptible host cells as shown before for clinical  
272 variants of BKPyV- and JCPyV-NCCRs (30, 33).

273 Finally, we noted that HPyV-NCCR expression levels differed in different host cell lines  
274 emphasizing that the combined cellular make-up of transcription factors and other regulatory  
275 proteins is essential in sensing and interpreting the HPyV-NCCRs with respect to viral gene  
276 expression and persistence (37). As this work was in progress, Moens and colleagues  
277 independently reported the characterization of HPyV-NCCRs in different cell lines using a  
278 unidirectional luciferase reporter assay, which also identified higher EVGR-expression by MCPyV-  
279 and HPyV12-NCCRs as well as by TSPyV-NCCR (53), but the latter was not confirmed in our  
280 study. Although uni-directional reporter assays have been commonly and successfully used to  
281 study uni-directional cell and viral promoters, they remain challenging for a bi-directional gene  
282 expression organisation within a small DNA sequence of approximately 500bp (**Fig.1**). Part of this  
283 stems from the difficulty to generate well-justified and controlled truncations of the intricate  
284 intertwined and competing functional elements of the bi-directional HPyV-NCCR (44, 45), which  
285 may-be difficult to accomplish given the pronounced effects of NCCR point mutations (44) and  
286 even simple rearrangements seen. Together with our previous analyses (30, 33), we are confident  
287 that the bi-directional reporter assays used here recapitulates the HPyV-NCCR activity, which can

288 be robustly enumerated in single cells using flow cytometry and includes estimates of non-  
289 transfected non-fluorescent cells (44, 45).

290 Our comprehensive analysis of the bi-directional HPyV-NCCR reporter expression using flow  
291 cytometry provides also estimates for different model cell lines derived from kidney, skin, lung,  
292 cervix, colon, and brain. The results suggest that there may be underlying mechanisms linked to  
293 cell differentiation and the respective HPyV-NCCR as expected for a co-evolutionary relationship.  
294 Thus, EVGR expression of MCPyV-NCCR was even stronger in skin-derived cell line A375 than  
295 in the kidney derived reference HEK293 or 293T derivative, whereas that of BKPyV-NCCR was  
296 strongest in kidney-derived, and that of WUPyV in colon-derived cell lines (**Table 1**). Although  
297 identifying these promoting or restricting factors in the respective cell lines require further study,  
298 their non-random expression profile is intriguing and suggests a first functional characterization of  
299 secondary HPyV host cell tropism through this bi-directional reporter assay. The combination of  
300 host cell and HPyV-NCCR reporter vector should be amenable to molecular screening approaches  
301 using loss-of-function e.g. through shRNA knock-down libraries, or gain-of-function approaches  
302 e.g. through expression library, or corresponding small compound libraries. Clearly, our correlation  
303 of functional response and NCCR sequence does presently not allow to simply delineate  
304 candidate sequences or factors, but requires fine mapping of major transcription factors binding  
305 sites as done for the BKPyV-NCCR (44) through further systematic work. In this regard, the current  
306 deficiencies of straight-forward HPyV culture and replication models must be acknowledged as a  
307 limitation. This obstacle is somewhat at odds with the rather frequent detection of certain HPyVs  
308 such as HPyV6 and HPyV7 on healthy skin and the rather poor NCCR-expression levels observed  
309 here as well as by others, and suggest that important host cell factors must be identified first before  
310 cell culture work can be successful.

311 The high number of HPyVs in humans continues to surprise (54), as comprehensive serological  
312 studies using specific Vp1-based IgG detection indicate that most humans have been infected

313 with more than one (17-19, 55), whereby serological evidence points to an average of 6 to 7 HPyV  
314 co-infections (19), some which may co-exist in the same organ as shown for skin and kidney, and  
315 may show direct positive and negative viral interactions (54).

316 In summary, the HPyV-NCCR mediates key functions of polyomavirus biology including  
317 persistence of the episomal viral genome in the host cell nucleus as well as timing and sequential  
318 steps of the viral replication cycle. Despite some limitations, our results are informative and  
319 represent an important step towards understanding secondary HPyV cell tropism beyond HPyV  
320 surface receptors. Using this approach raises novel perspective of identifying key viral and host  
321 factors shaping the viral life cycle, and for developing models of HPyV infection, replication,  
322 disease to identify suitable antiviral targets.

323

324 **ACKNOWLEDGEMENT**

327 manuscript.

328 **MATERIALS AND METHODS**

329 **HPyV NCCR and reporter constructs**

330 Based on the pHRG1 reporter vector (30) recapitulating the principle HPyV genome organisation  
331 with respect to EVGR and LVGR (**Fig. 2A**), a smaller bi-directional reporter pRG13D12 was  
332 constructed, in which the expression cassette for hygromycin resistance was removed, and the  
333 reporter genes were placed upstream of SV40 polyadenylation sites instead of those from beta-  
334 globin (**Fig. 2B**). The HPyV-NCCRs were chemically synthesized in pUC57 (Eurogentec S.A,  
335 Belgium) (**Table S1**) and excised using the restriction enzymes BssHII and MluI (New England  
336 Biolabs, England), and cloned into the corresponding restriction sites of pRG13D12. HPyV-NCCR  
337 constructs were verified by Sanger sequencing for correct NCCR sequence and orientation using  
338 the 3130 Genetic Analyzer (Applied Biosystems, Switzerland).

339

340 **Cell lines**

341 The cell lines, their origin and providers, and the standard culture conditions are listed in **Table 2**.  
342 All cell lines were cultured in a HERA cell-150 incubator (Thermo Fischer Scientific, Switzerland)  
343 at a temperature of 37°C and 5% CO<sub>2</sub>.

344

345 **Transfection**

346 Cell transfection was done in a ratio of 1:3 DNA to transfection reagent using 3µL Lipofectamine  
347 2000 (Thermo Fisher Scientific) and 1µg HPyV NCCR reporter constructs in a 12 well plate, except  
348 for SW480 cells that were transfected with 3µL Lipofectamine3000 (Thermo Fisher Scientific) and  
349 1µg HPyV NCCR reporter constructs. For each well, 3µl of lipofectamine2000 (or  
350 lipofectamine3000) was diluted in 100µl of Opti-Mem (Thermo Fisher Scientific) medium, flicked,  
351 spun down and incubated at room temperature (RT) for 5 minutes. 1µg of plasmid DNA was diluted  
352 in 100 µl of Opti-Mem medium for each well. Transfection reagents and plasmid DNA were then  
353 mixed, incubated for 5 minutes at RT and added to the cells with a confluency ranging between

354 70-90%. 24 h post-transfection (hpt), medium was replaced with DMEM with 10% FBS or DMEM-  
355 H with 10% FBS complemented with 2mM Glutamine. 48 hpt, fluorescence images were taken by  
356 fluorescent microscopy and EVGR (RFP) and LVGR (GFP) expression was quantified by flow  
357 cytometry.

358

#### 359 **Flow cytometer-based quantification**

360 Cells were washed once at 48 hpt with 1mL PBS/2.5 mM EDTA (BioConcept, Switzerland) and  
361 then treated with trypsin (without phenol red)/0.25mg/mL EDTA (Lonza, MD, USA). The cells were  
362 suspended in 1mL DMEM (without phenol red) containing 20mM HEPES, 2mM Glutamine, 1%  
363 FBS and 1% Penicillin/Streptomycin (P/S) (Thermo Fischer Scientific, Switzerland) and  
364 transferred to 5 mL polystyrene round-bottom tubes (BD, Franklin Lakes, NJ, USA). Prior to each  
365 measurement, DAPI (D8417, Sigma-Aldrich, St. Louis, MO, USA) was added to mark dead cells  
366 in a final concentration of 1 ng/mL. A Fortessa Cytometer (Becton-Dickinson, Franklin Lakes, NJ,  
367 USA) was used as follows: For RFP, excitation 561 nm (Yellow-Green Laser), emission 586/15  
368 nm; for GFP, excitation 488 nm (Blue Laser), emission 530/30 nm; DNA staining with DAPI,  
369 excitation 405 nm (Violet Laser), emission 450/50 nm. Transfection with pUC19 was used to set  
370 the gates for non-fluorescent transfection control cells in quadrant Q3, the cell numbers in the  
371 corresponding quadrants were determined (Q1 for red-only cells; Q2 for red and green cells; Q3  
372 for non-fluorescent cells; Q4 for green-only cells). The number of fluorescence cells for red, green  
373 and both were calculated as follows: red = number of cells in Q1 and Q2, green = number of cells  
374 in Q2 and Q4, red and green = number of cells in Q2. The mean fluorescence intensities (MFI) for  
375 EVGR (red) and LVGR (green) expression were calculated by inserting the cell number (N), mean  
376 fluorescence (I) of the quadrants Q1 (red cells only), Q2 (red and green cells), and Q4 (green cells

377 only) into the respective formulas:  $MFI(\text{red}) = \frac{(N_{Q1} * I_{Q1}) + (N_{Q2} * I_{Q2})}{(N_{Q1} + N_{Q2} + N_{Q4})}$ ;  $MFI(\text{green}) = \frac{(N_{Q2} * I_{Q2}) + (N_{Q4} * I_{Q4})}{(N_{Q1} + N_{Q2} + N_{Q4})}$ .

378 EVGR-expression of all HPyV constructs was normalized to the EVGR (red) and LVGR (green)

379 expression of the archetype BKPvV-NCCR(ww) set as 1 and 100%, respectively. Dot plot images  
380 from flow cytometer were processed in Adobe Illustrator CS4 14.0.0.

381

382 **LT-Ag expression in 293 cells stably transfected with MCPyV early gene region (293MCT**  
383 **cells).** 293 cells were transfected with 100ng linearised plasmid DNA encoding for MCPyV early  
384 gene region. After puromycin selection cells were lysed and analyzed by immunoblotting for  
385 MCPyV LTag expression using the mouse monoclonal MCPyV LTag antibody Cm2B4. Equal  
386 protein amounts loaded (30µg) were ensured by reincubating the membrane with an anti-actin  
387 antibody, Chemicon Cat.No.1501 (lower Blot). Parental cell line 293 negative for MCPyV LTag  
388 expression was used as a control on the immunoblot.

389

#### 390 **In silico analysis of HPyV NCCRs**

391 The MatInspector software tool (Genomatix, Munich, Germany)(46) was used to search for  
392 potential transcription factor- and LTag-binding sites within the HPyV NCCR. The NCCR  
393 sequences were uploaded into the MatInspector software tool using the settings described for  
394 BKPvV (45). For the identification of potential LTag binding sites the consensus sequence  
395 GRGGC (where R = A or G) was used allowing no mismatch.

396

#### 397 **Statistics**

398 The mean and standard deviations were calculated from three independent transfections using  
399 Microsoft Office Excel for Mac 2011 and GraphPad Prism software (version 7.0c for Mac OS).  
400 Multiple comparisons 2-way ANOVA was used for calculating the statistical differences between  
401 NCCR reporters construct expression in different cell lines, and 2-way comparisons as  
402 appropriate. Correlation analysis was done by non-parametric Wilcoxon test, or log-linear  
403 Spearman regression.

404

#### 405 **APPENDICES**

411 **Table 1: NCCR expression in different cell lines derived from kidney, skin, lung, cervix,**  
 412 **colon, brain and colon.**

413 EVGR- and LVGR-expression in the transfected cell lines indicated.

414 Top row lists mean fluorescence intensity of BKPyV(ww) in the indicated cell lines, which was  
 415 used for normalization to 1 for EVGR, and as 100 for LVGR levels.

423 **NCCR of 13 HPyVs.** The BKPvVww NCCR was used as the reference as described in Materials  
424 & Methods (45). HPyV-NCCR length is shown in the brackets in base pairs (bp). The direction of  
425 EVGR and LVGR transcription and the start codon (ATG) is depicted in red and green arrows,  
426 respectively. TSS, transcription start sites in dashed arrows, inr, initiation element in shaded grey  
427 rectangle; DPE, downstream promoter element in blue shaded rectangle; binding sites are shown  
428 as red triangle, LTag; yellow triangles, Sp1; green triangles, NFkB; black square, TATA-box; grey  
429 square, TATA-like element; blue triangles, NF1; orange triangles, Ets1; light orange triangles, Spi-  
430 B; ori, origins of replication in pink rectangles.

431

432 **Fig. 2: Rearranged BKPvV Dunlop NCCR showed higher EVGR-expression compared to**  
433 **BKPvVww NCCR in HEK293 cells.**

434 (A) Schematic representation of HPyV genome showing the noncoding control region (NCCR),  
435 early viral gene region (EVGR) in red encoding large and small T antigens (Tags), alternatives  
436 splice Tags; micro RNAs in blue arrow; late viral gene region (LVGR) encoding structural proteins  
437 (Vp1, Vp2, and Vp3), and the agnoprotein (agno) only in BKPvV and JCPvV.

438 (B) Representation of the bidirectional reporter vector, pRG13D12 containing the NCCR (in grey)  
439 in the early to late orientation cloned via restriction sites MluI and BssHII; red fluorescence protein,  
440 dsRed2 as a marker of EVGR-expression; green fluorescence protein, EGFP in opposite  
441 orientation, as a marker of LVGR-expression; SV40 polyadenylation signals (SV40 polyA) for the  
442 dsRed2 and EGFP expression cassette; E1 ori for bacterial plasmid replication; ampicillin resistant  
443 gene (Amp) for selecting *E.coli* transformants.

444 (C) Flow cytometry of HEK293 cells 2 dpt with pRG13D12 reporter vector containing the archetype  
445 BKPvVww-NCCR or the BKPvV(DUN)-NCCR-Fw cloned in forward orientation or BKPvV(DUN)-

446 NCCR-Rev cloned in reversed orientation. x-axis, EGFP fluorescence, y-axis, dsRed2  
447 fluorescence, 10,000 control transfected cells were gated for the live gate while 5,000 transfected  
448 cells were gated for the P3 (Q<sub>1</sub>, Q<sub>2</sub> and Q<sub>4</sub>) gate. Q<sub>1</sub>, Q<sub>4</sub> and Q<sub>2</sub> depict cells expressing red, green  
449 and both respectively. Ex, excitation wavelength; Em, emission wavelength.

450 (D) Quantification of cells: red bars, sum of red cells (Q<sub>1</sub>+Q<sub>2</sub>); green bars, sum of green cells  
451 (Q<sub>2</sub>+Q<sub>4</sub>); yellow bars red- and green-fluorescence double-positive cells (Q<sub>2</sub>); grey bars non-  
452 fluorescence cells (Q<sub>3</sub>, negative). Mean with SD of three independent replicates shown.

453 (E) Normalized mean fluorescence intensity (MFI). The weighted MFI was calculated for each  
454 measurement (see formulas in Materials and Methods), late expression was normalized to  
455 BKPyVww NCCR (green MFI set as 100) while early expression normalized to BKPyVww NCCR  
456 (red MFI set as 1). Mean with SD of three independent replicates shown.

457

458 **Fig. 3: HPyV-NCCR differ in EVGR-expression in HEK293 and 293T cell lines.**

459 (A) HEK293 normalized to archetype BKPyV(ww); (B) HEK293T cells normalized to archetype  
460 BKPyV(ww); (C) Fold change in 293T versus HEK293 cells; error bars (SD of three independent  
461 replicates); (D) Log-linear regression (y-log, x-linear) of LTag-binding sites and EVGR-expression  
462 in 293T cells.

463

464 **Fig.4. MCPyV-NCCR response in MVPyV T-antigen expressing 293MCT.**

465 (A) MCPyV-LTag expression in 293MCT cells

466 (B) Flow cytometry of MCPyV-17b and MCPyV-MCVw156;

467 (C) EVGR-expression presented as fold change in HEK293 cells;

468 (D) LVGR-expression expressed as fold change in HEK293 cells; mean with SD of three  
469 independent replicates shown; Wilcoxon-t-test.

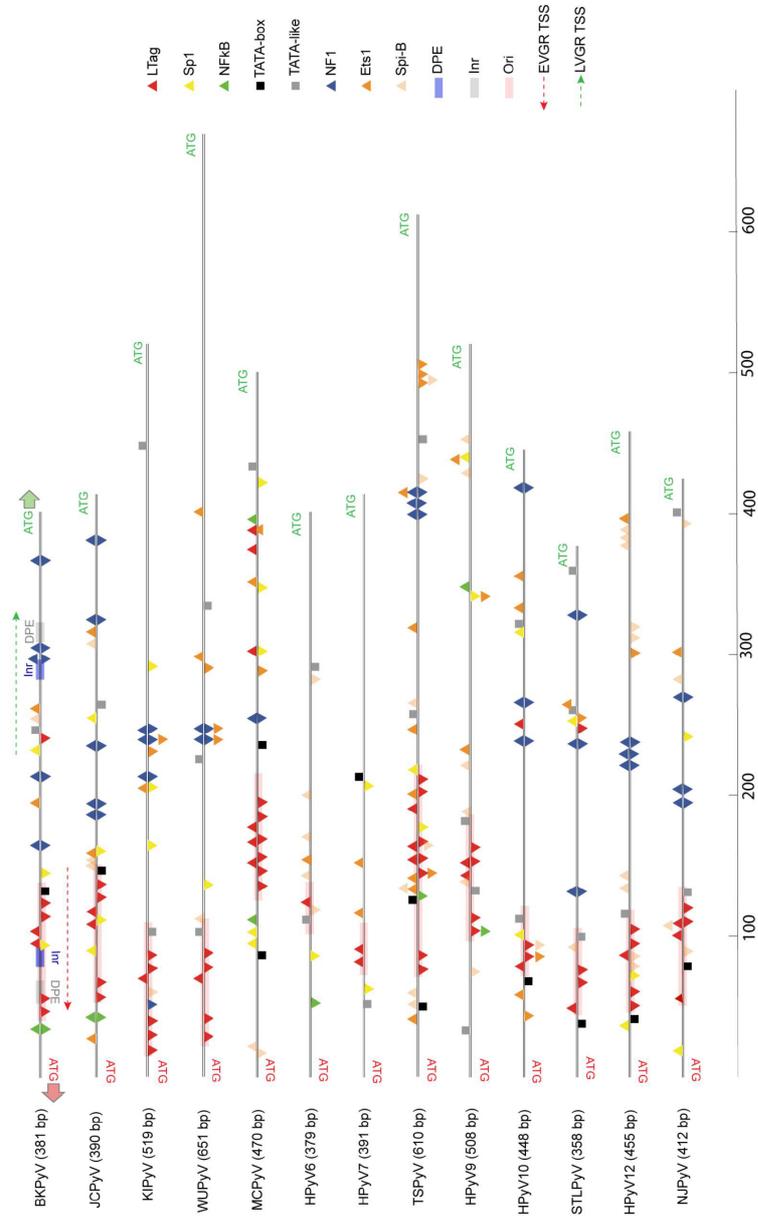

470

471 **Fig. 5 Clinical NCCR rearrangements of HPyV7 and HPyV9**

472 (A) HPyV7-PITT1 carries a 16 bp insertion (ins); HPyV7-PITT2 carries a 12 bp deletion (del, dotted  
473 line) compared to the archetype HPyV7-NCCR shown in Fig.1 EVGR- and LVGR-expression  
474 shown as fold change in HEK293 or SW480 cells, respectively. Mean with SD of three  
475 independent replicates shown; Wilcoxon t-test.

476 (B) HPyV9-UF1 carries an insertion providing 3 additional Sp1 sites compared to archetype  
477 HPyV7 shown in Fig 1. EVGR- and LVGR-expression shown as fold change in HEK293 or A549  
478 cells, respectively. Mean with SD of three independent replicates shown; Wilcoxon t-test.

The data demonstrated that the NCCR of HPyVs is different in length, number and position of LTag and TFBS composition, which drive the differential bi-directional expression. This disparity in the NCCRs-driven expression in different cell lines is also due to the transcription factors (TFs) make-up in the cell lines. Some HPyVs presented with high EVGR or LVGR expression in cell lines derived from tissues, where they were reported to have tropism for or detected in. For instance, BKPyV and JCPyV known to have tropism for kidney and brain had highest EVGR in the kidney derived cells HEK293 or the brain derived cells HS683, respectively. MCPyV, suspected to have tropism for the skin, displayed its highest EVGR expression in the skin-derived A375 cells. While HPyV12 discovered from the liver of a colon carcinoma patient revealed a higher EVGR expression in the colon derived SW480 cells. However, others showed high activity in cell lines derived from tissues where they have not so far been detected. This indicates that these HPyVs could have tropism for the body compartments where the cell lines were derived from or may be replicated in, however, this remains to be tested. BKPyV, JCPyV and MCPyV have been efficiently replicated in cell lines expressing SV40 or MCPyV Tags, respectively (305). SV40 Tags activated EVGR expression of HPyVs and MCPyV cognate Tags activated EVGR expression from the MCPyV NCCRs, indicating cell lines expressing cognate Tags of respective HPyVs could be used for their propagation. Analyses of rearranged NCCR variants for BKPyV and JCPyV have been greatly investigated (25, 26). We reported that rearranged NCCR variants of novel HPyVs (HPyV7 and HPyV9) derived from patients increased EVGR as reported for BKPyV and JCPyV (25, 26) reiterating the NCCR as the pathogenicity determinant. Interestingly, even the rearranged NCCR variants of novel HPyVs demonstrated varied activity in different cell lines, indicating the host cell TFs make-up are also involved in the NCCR-driven viral expression. Our data are important for identifying host and viral factors necessary for culturing HPyVs and prediction of HPyVs secondary host cell tropism.

This work was performed together with Christian Baumann.

### **5.3 Point mutations in the large T antigen binding sites of BK polyomavirus non-coding control region affect gene expression**

#### **ABSTRACT**

The non-coding control region of all human polyomaviruses contain the origin of viral replication, which is made up of binding motifs for large T antigen (LTag). LTag interacts with these motifs to mediate viral genome replication and activation of late viral gene region (LVGR) expression as already described for the SV40. Since the LTag binding motifs between SV40 and BK polyomavirus (BKPyV) at the ori are the same, we hypothesised that the effect of LTag-binding sites mutageneses in BKPyV NCCR would be similar to that of SV40. We compared the EVGR and LVGR expression of BKPyV archetype (ww) NCCR defective in one or more LTag binding sites using a bidirectional reporter vector in HEK293 cell lines expressing no, small or large amounts of SV40 LTag. Our results demonstrated an increase in early viral gene region (EVGR) expression in all mutants in both HEK293T and HEK293TT cells compared to HEK293 cells. The EVGR expression increase was less in HEK293TT cells compared to HEK293T cells, however, mutants containing mutant A showed a lesser decrease of EVGR expression in HEK293TT cells compared to all other mutants without mutant A. Furthermore, mutants harboring mutant A displayed higher levels of EVGR expression compared to other mutants in both HEK293T and HEK293TT cells. Conversely, LVGR expression increase proportionally in HEK293T and HEK293TT cells; respectively. Nonetheless, mutants harboring A and D mutations, abrogated the further increase of LVGR in HEK293TT cells.

## INTRODUCTION

Polyomaviruses (PyVs) belong to the family *Polyomaviridae*, they are double-stranded DNA (dsDNA) viruses with small circular genomes of approximately 5 kb (328). The genome is encapsidated in an icosahedral capsid of approximately 45 nm (1). The genome of PyVs is divided into 3 main regions: The early viral gene region (EVGR), late viral gene region (LVGR) and the non-coding control region (NCCR) (329). The EVGR encodes small and large T antigens (sTag and LTag), while the LVGR encodes viral structural proteins. The LTag possesses multifunctional roles, such as initiation and maintenance of viral genome replication, regulation of EVGR and LVGR expression, and assembly of virions (59, 330-332). Additionally, LTag leads to transformation by interacting with tumour suppressor proteins such as retinoblastoma proteins (pRB) and p53 (333). PyVs' sTag has been reported to be implicated in the transformation role of LTag (18, 260, 264). The NCCR of HPyVs of approximate 400-600 base pairs (bp) in length is located between the EVGR and the LVGR. The NCCR harbours LTag binding motifs mostly at the origin of viral replication (ori), a numerous transcription factor binding sites (TFBSs), enhancers, EVGR and LVGR promoters, which initiate and regulate the bidirectional expression of PyVs. The NCCR of BK polyomavirus (BKPyV) is approximately 400 bp. The archetype (ww) BKPyV NCCR is made up of linear sequence blocks arbitrarily denoted as O<sub>146</sub> (containing the ori), P<sub>68</sub>, Q<sub>39</sub>, R<sub>63</sub>, and S<sub>63</sub> (subscript numbers represent number of nucleotides). Two kinds of BKPyV NCCR architectures have been identified, ww- and rearranged (rr-) NCCRs. The rr-NCCRs consist of sequence deletions, duplications, or combinations of both. The rearrangement frequently occurs in the LVGR promoter side, while the EVGR promoter side containing the ori remain intact (22). The rr-NCCRs of BKPyV and JCPyV variants from patients suffering from BKPyV-associated nephropathy (BKPyVAN) and progressive multifocal leukoencephalopathy (PML), have been demonstrated to be associated with increased EVGR expression and viral replication (25, 26). The ori of PyVs is located in the NCCR, proximal to the EVGR side (49). The role of each LTag binding sites within the ori of HPyVs have not been well characterized, unlike in the monkey polyomavirus SV40 (59). The SV40 ori is consist of pentanucleotide sequences (5'-GRGGC-3' or 5'-GCCYC-3'), which are found at the oris. LTag interacts with these

pentanucleotide sequences via the origin-binding domain (OBD). This OBD is about 50% identical among HPyVs and can activate transcription (334). Furthermore, this protein melts and unwind the dsDNA in an ATP-dependent manner. Additionally, other host's factors such as topoisomerase I, polymerase alpha primase complex and replication factor A are recruited by LTag to the site of replication initiation (335, 336). Additional functional domain of the LTag, such as the DnaJ domain plays a vital role in viral genome replication *in vivo* (337), however, dispensable for viral replication *in vitro* (338). The SV40 ori is made up of two LTag binding motifs proximal to the EVGR with the ori referred to as *site I*, and four centrally located LTag binding sites referred to as *site II* (59). The SV40 minimal ori is characterised by three sequence motifs that is, a centrally located four-pentanucleotide repeats (*site II*), a poorly conserved early palindrome (EP) sequence proximal to the early side of the ori, and a conserved AT-rich sequence near the late side of the ori (49). The SV40 ori is made of 2 LTag binding motifs on the early side of the ori called *site I*, and four centrally located LTag binding sites called *site II* within the ori (49). A similar ori organization is found in BKPyV ww, JCPyV ww, Merkel cell polyomavirus, human polyomavirus 9, human polyomavirus 12 (49). As reported for SV40, each base pair of the pentanucleotide sequence is critical for LTag binding and viral replication (59). However, adjacent sequences to these LTag binding sites have little or no influence on the binding of LTag and viral replication (59). This suggests that the pentanucleotide sequence at the viral ori is the fundamental functional unit for LTag binding and viral DNA replication (339). Adjacent LTag binding sites increase the stability of LTag binding. In SV40, the main function of LTag binding to *site I* is the auto-regulation of EVGR expression (59). LTag binds to *site I* and represses the transcription of EVGR, whereas the function of *site II* is to bind and position LTag in the correct orientation and location for its function in viral genome replication (59). The 6 LTag binding sites near the EVGR side of BKPyV ww are similarly organized compared to the 6 LTag binding sites of SV40 (49). The roles of the SV40 LTag motifs in the regulation of the SV40 bidirectional expression have been well described (59), however, very little is known about that of BKPyV. The LTag binding motifs between SV40, BKPyV and JCPyV at the ori are the same, we hypothesize that the role of the LTag binding motifs in BKPyV is similar to that of SV40 (49). In order to elucidate the role of BKPyV LTag-binding motif, we compared in a

bidirectional reporter vector the EVGR and LVGR expression of BKPyV ww NCCR with those of BKPyV ww NCCR defective in one or more LTag-binding motif in HEK293 cells expressing none, a small or large amounts of SV40 LTag. Our results showed the mutants containing mutant A displayed a lesser decrease in HEK293TT cells compared to other mutants. While the LVGR expression proportional increase is abrogated for mutants harboring mutants, A and D.

## RESULTS

### LTag mutagenesis and mutant naming

We identified by MatInspector software seven LTag binding sites (Fig. 1). Six of these sites are contained in the ori and are similarly organized compared to the six LTag binding sites of SV40 (49). We performed different mutageneses within the LTag-binding sites in the BKPyV ww NCCR by substituting the first two bases of the sites as follows; (G->T, C->A or vice versa), and the mutant NCCRs were reanalyzed by MatInspector for LTag binding, while allowing 2 mismatches. *In silico* analyses indicated no LTag binding after introducing two substitutions. To ease naming of the mutants, we assigned the DNA strand that goes in 5' to 3' direction from the EVGR via the NCCR to the LVGR as the *forward strand*. Likewise, we named the strand that goes in 5' to 3' direction from the LVGR through the NCCR to the EVGR as the *reverse strand*. Two sites were identified on the *forward strand* (pink) (5'-GRGGC-3') and five on the *reverse strand* (yellow) (5'-GCCYC-3') (Fig. 1). The BKPyV contains 6 LTag binding sites within the ori (49). Two LTag binding sites referred to as *site A* proximal to the EVGR (*site I* in the SV40 nomenclature) and four centrally located motifs are found adjacent to an AT-rich sequence referred to as *site B* and *C* (*site II* in the SV40 nomenclature) (49). These 4 sites contained two forward motifs referred to as *site B* and two reverse motifs referred to as *site C* in the BKPyV nomenclature. The *B* and *C sites* are each separated by one nucleotide as shown for SV40 (49). Finally, the LTag binding site outside the ori, referred to as *site D*, is proximal to the LVGR side (Fig.1). All the other LTag binding sites on the *reverse strand* contain a thymine at the fourth position of the reversed motifs 5'GCCYC'3 except LTag binding *site D*, which contains a cysteine instead of a thymine at this position. LTag binding sites in close proximity and on the same strand were mutated together. This provided a total of four possible LTag binding site mutants, which were labelled A (R1 and R2), B (F1 and F2), C (R3 and R4) and D (R5), where 'R' stands for reverse and 'F' for forward, while the numbers are the motifs numbering from EVGR to the LVGR (Table S1). *D site* was the only single site mutated alone (Table S1). Altogether, eight different mutants including combination of the different LTag binding site mutants were made (Table S1). The LTag binding mutagenesis affected some TFBS within the NCCR. However, apart from binding sites for E2F4 and Sp1 (highlighted in yellow)

affected due to D mutation, most of the TFBS affected are not found in the kidney (Table S2).

### **Effect of LTag binding site mutants on EVGR and LVGR expression in HEK293 cells**

To examine the effect of the different NCCRs defective of LTag binding, we cloned them in the bidirectional reporter vector pRG13D12, transfected HEK293 cells and measured the EVGR and LVGR expression by flow cytometry. Mutation of *B*, *C* and *D sites* showed a gain of function for EVGR expression in HEK293 cells, while all other mutant combination containing *A site* mutation presented with a loss of function for EVGR expression compared to the un-mutated archetype. Conversely, mutant combinations containing mutation in *A* or *D site* alone, revealed a loss of function for LVGR expression compared to the archetype. Whereas, the LVGR expression of mutants, *B* and *C sites* showed little or no effect.

### **Effect of LTag binding site mutants on EVGR and LVGR expression in HEK293-derivative cell lines that constitutively expressing SV40 LTag in different amounts**

To measure the effect of the different LTag binding site mutants in the presence of small and large amounts of LTag, we transfected HEK293, HEK293T and HEK293TT cells constitutively expressing none, a small or large quantity of LTag (Fig. 3). Two days post transfection we analyzed the EVGR and LVGR expression by flow cytometry as previously described (34). Furthermore, we calculated the EVGR MFI of each construct normalized to their corresponding EVGR MFI in HEK293 cells set as 1. Our result depicted 3 distinct groups based on EVGR expression patterns (Fig. 3A). We could identify group wwE (mutants with similar EVGR expression pattern as archetype), group A (all mutants harboring mutation A) and group D. Compared to the corresponding expression in HEK293 cells, all groups exhibited a gain of function for EVGR expression in HEK293T cells. The EVGR expression in HEK293TT cells in the 3 groups were as follows; for group wwE the EVGR expression was reduced to the levels in HEK293 cells, while for group A it remained at similar levels to the corresponding levels in HEK293T cells and lastly, for group D the level was reduced

below the corresponding expression in HEK293 cells (Fig.4A). In addition, mutants containing *A site* mutation generally showed higher EVGR expression fold in both cell lines expressing LTag compared to other mutants (Fig. 4A). Mutations in *A site* presented with very slight decrease of EVGR in HEK293TT cells compared to other mutations (Fig.4A). This implies that abolishing LTag interaction to the *site A* by mutagenesis prevents the EVGR expression decrease in HEK293TT cells as seen for other mutants in combination with *A site* mutant.

We also calculated the LVGR MFI of each construct normalized to their corresponding LVGR MFI in HEK293 cells set as 1. With respect to the LVGR, we were able to identify 2 different groups regarding LVGR expression patterns, in particular group wwL (mutants with similar LVGR expression pattern as archetype) and group AD (all mutants harboring both mutation A and D). Compared to corresponding expression in HEK293 cells both groups revealed a gain of function for LVGR expression in HEK293T and HEK293TT cells. However, all except mutants containing A and D mutations displayed a proportional LVGR expression corresponding to increasing amounts of LTag (Fig. 4B). This indicates that mutation in both *A* and *D sites* together abrogated further LVGR activation in HEK293TT cells. Interestingly, mutants with either A or D alone still permitted the LVGR activation in HEK293TT cells (Fig. 4B), thus indicating a cooperative action of LTag interaction to both sites to increase LVGR expression in the presence of high amounts of LTag expression.

## DISCUSSION

Here we report that reduced-EVGR expression in the presence of large amounts of LTag expression can be via LTag binding *site A*, LVGR expression increase can be via both *sites A* and *D*. The oris of the 13 HPyVs has been reported (49). The number, orientation and spacing of LTag binding motifs at the ori of SV40, BKPyV and JCPyV are the same (49). SV40 and BKPyV core oris contain 4 centrally identical LTag binding motifs termed *site II* with respect to SV40 and *site B, C* with respect to BKPyV nomenclature (49). The two other motifs located proximally to the EVGR termed *site I* with regard to SV40 and *site A* with respect to BKPyV nomenclature are separated by 7 A-rich bps. BKPyV has a 7<sup>th</sup> LTag binding motif termed D motif located proximal to the LVGR side (Fig.1). Other HPyVs such as, MCPyV, HPyV10 and STLPyV also encode LTag binding motifs outside their oris, proximal to the LVGR side (Fig. 1 section 5.1). However, the role of these sites is yet to be elucidated.

Since the roles of the SV40 LTag motifs with respect to regulation of EVGR and LVGR and viral genome replication are well known and the motifs between SV40, BKPyV and JCPyV at the ori are the same, we hypothesize that mutageneses of BKPyV's LTag-binding sites will show similar effect compared to SV40. We analyzed EVGR and LVGR expression of BKPyV ww NCCR defective in one or more LTag-binding sites compared to BKPyV ww-NCCR in HEK293 cells expressing none, a small or large amount of SV40 LTag.

To get an indication of the effect of the LTag mutants in the absence of LTag, we analyzed the EVGR and LVGR expression in HEK293 cells. All mutations harboring *site A* mutagenesis displayed a loss of function for EVGR, while mutants *B, C, and D* showed a gain of function for EVGR expression compared to BKPyV ww-NCCR (Fig. 2A), suggesting that mutagenesis of *site A* may results in a loss of activating transcription factor binding sites (TFBS) or gain of repressing TFBS (Table S2). However, the reverse could be plausible for the other mutants. On the other hand, mutants *A, D* and mutants harbouring *A site* mutation exhibited a loss of function for LVGR expression, whereas mutant *B* and *C* has little or no effect, indicating a loss of activating TFBS once the *A* and *D sites* were mutated. Specifically, mutation in the *D*

*site* showed an *in-silico* loss of Sp1 and E2F4 binding, which were the only affected factors found in the kidney (Table S2). This is in line with the published work of Bethge et al., whereby Sp1-4 core site mutagenesis led to an increase in EVGR in expense of LVGR expression (340). However, our results were not exactly the same compared to that of Bethge et al, which could be due to the fact that the D site mutation did not affect the Sp1-4 core binding site, suggesting Sp1 may still be interacting with the binding site in a reduced affinity.

Next, we investigated the effect of these NCCR-mutants defective in LTag binding in HEK293 cells producing small and large amounts of SV40 LTag, HEK293T and HEK293TT cells, respectively. Interestingly, all mutants including mutant combination where all LTag-binding sites were disrupted, showed higher EVGR expression in HEK293T cells compared to HEK293 cells. Moreover, the EVGR expression pattern between the different mutants were regulated differently in HEK293T and HEK293TT cells, resulting in the depiction of 3 different groups that is groups, wwE, A and D (Fig. 3A). Group A (mutants harbouring mutant A) generally shows higher EVGR expression in both HEK293T and HEK293T cells compared to other mutants, indicating that mutation of binding *site* A leads to gain of function for EVGR expression in the context of LTag expression as previously reported for SV40 with *site* I mutation (341). Intriguingly, all mutants including the mutant where all the LTag binding motifs were mutated (ABCD) presented with elevated levels of EVGR expression in HEK293T cell. Further studies are required to examine this elevation, which most probably do not involve LTag interaction to its binding sites, however, may reflect LTag inhibition of EVGR-negative regulatory factors or increase in plasmid copy numbers. However, our preliminary copy number quantification does not correlate with the EVGR expression (Fig. 4C).

Furthermore, we showed that EVGR expression of mutants in group wwE and D increased in HEK293T cells expressing small amounts of LTag and greatly decreased in HEK293TT cells expressing large amounts of LTag compared to mutants containing A mutation (group A). In summary, mutating the LTag-binding *site* A or combination of LTag-binding *site* A with other LTag-binding sites (group A) abrogated the EVGR-expression decrease, indicating a specific role of LTag-binding sites with respect to EVGR expression.

In addition, except mutants containing both *A* and *D* mutation (group AD) there was a proportionate increase in LVGR expression in the presence of increasing amounts of LTag expression, which was similarly described for JCPyV LVGR activation by SV40 LTag (342). This suggests that the proportionate increase of LVGR expression can be mediated via sites *A* and *D*, since mutants containing either *A* or *D* or other LTag binding sites still show this proportional increase in LVGR expression. Taken together, while LTag-binding site *A* can be involved in the decrease of EVGR expression in abundant LTag expression, LVGR expression can be increased by cooperative involvement of LTag-binding sites *A* and *D*. Interestingly, like the EVGR expression of all mutants including mutant ABCD displayed elevated levels of LVGR expression in HEK293T cells. However, the mechanism cannot be deciphered with this current study. However, LTag inhibition of negative LVGR regulatory factors or copy number effect can be suspected. A summary model of the results is depicted in Fig. 5.

Lastly, *site II* in SV40 is reported to play a role in SV40 replication, but not expression (59). Mutation of a corresponding site in BKPyV, sites *B* and *C*, showed little or no effect with respect to EVGR and LVGR expression in the context of LTag expression compared to the archetype, thus corroborating the SV40 results (59). Our current study cannot explain viral replication, Nonetheless, our preliminary copy number quantification does not correlate with the expression, indicating copy numbers might not play a role in the expression pattern depicted.

In this study, we analyzed the effect of SV40 LTag on the BKPyV ww-NCCR defective of LTag binding motifs. However, one cannot exclude that the BKPyV cognate LTag might give different results. Nonetheless, the SV40 and BKPyV LTag have great similarity, and the fact that BKPyV can replicate in Cos-7 cells constitutively expressing SV40 LTag argue against this possibility. Here, EVGR and LVGR expression were analyzed using the bidirectional reporter vector. Further experiments are required to quantify the viral replication potential of the various NCCR mutant defective of LTag binding motif by cloning in a Dunlop backbone and perform viral replication studies in cell culture. However, the fact that BKPyV and SV40 have similar LTag binding sites and show similar EVGR and LVGR expression regulatory mechanism via the LTag binding sites, suggests that results obtained from

studying BKPyV can be extrapolated to other HPyVs such as, JCPyV with similar LTag binding site organization.

## **MATERIALS AND METHODS**

### **Plasmids**

We used the bidirectional reporter vector designed a new-smaller bi-directional reporter pRG13D12 described, similar to the phRG reporter described in Gosert et al (25). The reporter lacks the SV40 early promoter, beta globulin poly-adenylation signals, Hygromycin gene present in the NCCR cloned in phRG (25). PUC57 vector containing HPyV NCCR without the 12-nucleotide sequence. NCCRs defective of LTag binding were purchased from Eurogentec (Eurogentec S.A, Belgium). The NCCRs were excised from the pUC57 vector by using the restriction enzymes BssHII and MluI (New England Biolabs, England). The NCCRs were cloned via the corresponding restriction sites in the bi-directional vector, pRG13D12. Constructs with the right NCCR were verified by the 3130 Genetic Analyzer Sanger sequencer (Applied Biosystems, Switzerland).

### **Cell lines**

The following cell lines, HEK293 cells (CRL1573, ATCC, Manassas, VA, USA), HEK293T cells (CRL3216, ATCC, Manassas, VA, USA), HEK293TT cells (0508000, NCI-Frederick Repository Service, Frederick, Maryland, USA), were grown in Dulbecco's modified Eagle's medium with high glucose (DMEM-H, D5671, Sigma-Aldrich, St. Louis, MO, USA) containing 10% FBS (S0113, Biochrome AG, Berlin, Germany) and 2mM L-glutamine (K0302, Biochrome AG, Berlin, Germany). The medium of HEK293TT cells was supplemented with 400µg/mL hygromycin B (Calbiochem, San Diego, CA, USA). The cells were cultured in a HERA cell-150 incubator (Thermo Fischer Scientific, Switzerland) at a temperature of 37°C and 5% CO<sub>2</sub>.

### **Western blot**

HEK293, HEK293T, and HEK293TT cells were lysed in triple-buffer (50 mM Tris-HCl [pH 8.0], 150 mM NaCl, 1% NaDOC, 1% Triton X-100 and 0.1% SDS) containing 1x protease inhibitors. Equal volume of 10µg of cell lysates were separated by SDS-PAGE using running buffer (50 mM Tris base, 199mM Glycine, 0.1% SDS, pH 8.3) at

25mA for 50 mins. The proteins were then electro-transferred (semi dry method) onto 0.45  $\mu\text{m}$  polyvinylidene difluoride (PVDF) membrane (IPFL00010; Millipore/Merck, Darmstadt, Germany) using 1x transfer buffer (10x: 48mM Tris base, 390m M Glycine, 10% SDS) at 70mA for 48 minutes. The membrane was dried, reactivated with 5 mL methanol (Sigma-ALDRICH, Switzerland) and washed with milli-Q  $\text{H}_2\text{O}$ . Odyssey blocking buffer (927-40000; Licor, Lincoln, NE, USA) diluted 1:2 in Tris-buffered saline (TBS) was used to block the membrane at RT for 1 h. Incubation of the membrane was done in the following primary antibodies: monoclonal mouse anti-actin (1:5'000; Abcam, Cambridge, England), polyclonal rabbit anti-LTag (1:10'000; Professor Christine Hanssen Rinaldo, University of North Norway in Tromsø, Norway), diluted in 1:2 Odyssey blocking buffer-TBS-0.1% Tween20 at 4°C overnight. The membrane was then washed at least 5x with TBS-0.1% Tween 20. Next, the membrane was incubated in the following secondary antibodies: donkey anti mouse Alexa Fluor 680 (1:15000; A10038; goat anti-rabbit antibody-IRDye 800CW (1:10,000; 926-32211; Licor), invitrogen) diluted in 1:2 Odyssey blocking buffer TBS, 0.1% Tween20 at RT for 1hr. The membrane was washed at least 3x with TBS-0.1% Tween20. Detection and quantification of protein was done with the Licor Odyssey CLx instrument (Licor, Homburg, Germany).

## **Transfection**

All cell lines were transfected with 3 $\mu\text{L}$  Lipofectamine 2000 (1734997, Invitrogen, Carlsbad, CA, USA) and 1 $\mu\text{g}$  plasmid DNA construct in a 12 well plate, according to manufacturer's instructions. Prior to transfection the cells' confluency ranged between 70-90%. 24 hrs post-transfection, medium was replaced with DMEM-H/10% FBS complemented with 2mM Glutamine. 48 hrs post-transfection, fluorescence images were taken by fluorescent microscopy and EVGR (RFP) and LVGR (GFP) expression quantified by flow cytometry.

## Flow cytometer-based quantification

Forty-eight-hour post-transfection cells were washed once with 1mL PBS/2.5 mM EDTA (BioConcept, Switzerland) and then trypsinized with trypsin (without phenol red) /0.25mg/mL EDTA (Lonza, MD, USA). The cells were suspended in 1ml DMEM (without phenol red) containing 20mM of HEPES, 2mM Glutamine, 1% FCS and 1% Penicillin/Streptomycin (P/S) (Thermo Fischer Scientific, Switzerland) and transferred to 5 ml polystyrene round-bottom tubes (BD, Franklin Lakes, NJ, USA). Prior to each measurement, DAPI (D8417, Sigma-Aldrich, St. Louis, MO, USA) was added as a dead-cell marker to a final concentration of 1 ng/ml. Fortessa Cytometer (BD, Franklin Lakes, NJ, USA) was used for the flow cytometry measurements. RFP, Excitation was 561 nm (Yellow-Green Laser), Emission was 586/15 nm; GFP, Ex. 488 nm (Blue Laser), Em. 530/30 nm and DAPI, Ex. 405 nm (Violet Laser), Em. 450/50 nm. The weighted mean fluorescence intensities (MFI) for EVGR (red) and LVGR (green) expression were calculated by inserting the cell number (N), mean fluorescence (I) of the quadrants Q1 (red cells only), Q2 (red and green cells), and Q4 (green cells only) into the respective formulas:  $MFI(\text{red}) = \frac{(N_{Q1} * I_{Q1}) + (N_{Q2} * I_{Q2})}{(N_{Q1} + N_{Q2} + N_{Q4})}$ ,  $MFI(\text{green}) = \frac{(N_{Q2} * I_{Q2}) + (N_{Q4} * I_{Q4})}{(N_{Q1} + N_{Q2} + N_{Q4})}$ . EVGR expression of all HPyV constructs was normalized to the EVGR of BKPyVww set as 1 while LVGR expression of all HPyV constructs was normalized to the LVGR of BKPyVww set as 1.

## Plasmid copy number quantification

Plasmid copy numbers were quantified after total DNA extraction from cells suspended in 200ul PBS. A QIAamp DNA blood kit (Qiagen Hombrechtikon, Switzerland) was used for the extraction according to the manufactural instructions. Quantitative PCR protocol for detecting dsRed2, primers and probes shown below was used.

The following primer and probe was used for the qPCR

	Sequence (5' – 3')	Length/%GC	Tm [°C]
Primer			
DsRed2_f	GGT GGA GTT CAA GTC CAT CTA CAT G	25 bp/48	57.1
DsRed2_r	CCA CGA TGG TGT AGT CCT CGT T	22 bp/54.5	58.7

### In silico analysis of BKPyV ww NCCR

The MatInspector software tool (Genomatix, Munich, Germany)(324) was used to search for potential LTag binding sites within the BKPyV ww NCCR. For identifying potential LTag binding sites the BKPyVww NCCR was uploaded into the software and the user-defined IUPAC string using the LTag binding site consensus sequence, GRGGC (where R = A or G) allowing no mismatch.

## Statistics

The Mean and standard deviations were calculated from three independent transfections using GraphPad Prism software (version 6 for Mac OS).

## FIGURE LEGEND

Fig. 1: **Presentation of BKPyV ww NCCR with putative LTag binding sequence motifs.** The LTag binding motifs are numbered from left to right (1-5) according to their respective orientations. (*R*= reverse and *F*= forward), binding site A contains 2 motifs (*R1* and *R2*), site B (*F1* and *F2*), site C (*R3* and *R4*) and site D (*R5*). The number of the bp of each site is depicted. Lastly, the EVGR and LVGR start codon (ATG) are shown on the reverse and *forward strands*, respectively.

Fig. 2: **Differential effect of LTag binding site mutants in HEK293 cells.** (A) MFI of EVGR expression normalized to EVGR MFI BKPyVww set as 1. (B) MFI of LVGR expression normalized to EVGR MFI BKPyVww set as 1. NCCR driven EVGR and LVGR expression measured by FACS and MFI calculated as described in materials and methods. Error bars represent standard deviation of three independent experiments.

Fig. 3: Western blot of LTag expression in HEK293, HEK293T and HEK293TT cell lines.

Fig. 4: **Downregulation of EVGR and upregulation of LVGR expression in abundant amounts of LTag.** (A) EVGR expression fold in HEK293T and HEK293TT cells normalized to corresponding EVGR expression in HEK394 cells set as 1. Based on EVGR expression patterns, 3 groups were depicted (groups wwE, A and D). (B) LVGR expression fold in HEK293T and HEK293TT cells normalized to corresponding LVGR expression in HEK394 cells set as 1. Based on LVGR expression patterns, 2 groups were depicted (groups wwE, AD). Error bars indicate standard deviation of three independent experiments.

**Fig. 5: A model depicting the effect of LTag-binding sites mutageneses.** (A) In HEK293 cells containing no LTag, host transcription factors (orange ovals) interact with the BKPyV ww NCCRs to maintain the bidirectional EVGR (red arrow) and LVGR (green arrow) expression balance. (B) In the presence of small amount of LTag in HEK293T cells (few yellow triangles), EVGR and LVGR expression is increased via an unknown mechanism, (LTag binding sites, A = inverted V in light blue, B and C = inverted V in thick blue and D = inverted U in pink), since the mutant with all LTag binding sites mutated, displayed higher levels of EVGR expression. This may reflect inhibition of EVGR and LVGR negative regulatory factors by LTag (pink oval in contact with yellow triangle). (C) In the presence of large amounts of LTag in HEK293TT cells, LVGR expression increase even more for all mutants except in mutants containing mutant A and D mutations. Indicating the addition increase is mediated via A and D sites. Whereas, EVGR expression decreases compared to the levels in HEK293T cells for all mutants except those harboring mutant A indicating that the reduced EVGR expression involves site A. B and C sites showed little or no influence of EVGR expression in HEK293 cells expressing LTag. The expression pattern is similar to that of the ww NCCR. These sites may be involved in viral replication as described for a homologous *site II* in SV40.

### 5.4 Imperfect symmetry of Sp1 and core promoter elements regulates early and late viral gene expression of the bi-directional BK polyomavirus non-coding control region

Specificity protein 1 (Sp1) has a crucial role in the transcription of both cellular and viral genes (343). All cells of the human body ubiquitously express this transcription factor (344). Sp1 binds to GC-box motifs found in SV40 and BKPyV NCCR and its binding is vital for the regulation of EVGR and LVGR expression (340). This GC-box motif is found on the NCCR of all HPyVs, suggesting a vital role for this sequence in the growing family of HPyVs. Our group reported a detailed point mutants of the BKPyV<sub>ww</sub> NCCR defective in 28 different TFBS without changing the overall BKPyV<sub>ww</sub>-NCCR length and architecture. A hierarchy of TFBS was identified, whereby 3 phenotypic groups were detected: group 1 TFBS mutations revealed activation of EVGR expression in expense of LVGR expression and strong replication rates similar to what was reported for BKPyV rr-NCCR variants from patients. Group 2 TFBS mutants displayed an intermediate phenotype with regards to EVGR expression and replication capacity, while group 3 showed reduced EVGR and LVGR expression and allowed modest or no viral replication (340).

Among all the TFBS, Sp1 sites revealed a prominent role in BKPyV NCCR-driven expression. BKPyV NCCR has at least 3 Sp1 binding sites; two of these sites (Sp1-2 and Sp1-4) appeared to have underlying opposite effects in the expression and replication of BKPyV. Mutagenesis of the Sp1-4 site proximal to the LVGR demonstrated a strong EVGR expression, whereas inactivation of Sp1-2 site proximal to the EVGR overrode both EVGR and LVGR expression. This effect of *sp1-2* mutant was also recorded in group 1 mutants including *sp1-4* mutant, indicating a vital regulatory role of SP1 in the NCCR as a whole (340).

The role of these two Sp1 sites and their relationship to core promoter elements in the BKPyV ww-NCCR was examined in greater detail. This role of Sp1 sites in BKPyV could be extrapolated to other HPyVs, especially those with similar Sp1 sites and core promoter elements (CPEs) architecture. We examined the bi-directional balance of EVGR and LVGR expression and viral replication with respect to Sp1-2 and Sp1-4 sites strand orientation, affinity and number of Sp1 sites. In addition, the contribution of EVGR and LVGR CPEs in EVGR and LVGR expression was also investigated

# Imperfect Symmetry of Sp1 and Core Promoter Sequences Regulates Early and Late Virus Gene Expression of the Bidirectional BK Polyomavirus Noncoding Control Region

## ABSTRACT

Rearrangements or point mutations in the noncoding control region (NCCR) of BK polyomavirus (BKPyV) have been associated with higher viral loads and more pronounced organ pathology in immunocompromised patients. The respective alterations affect a multitude of transcription factor binding sites (TFBS) but consistently cause increased expression of the early viral gene region (EVGR) at the expense of late viral gene region (LVGR) expression. By mutating TFBS, we identified three phenotypic groups leading to strong, intermediate, or impaired EVGR expression and corresponding BKPyV replication. Unexpectedly, Sp1 TFBS mutants either activated or inhibited EVGR expression when located proximal to the LVGR (*sp1-4*) or the EVGR (*sp1-2*), respectively. We now demonstrate that the bidirectional balance of EVGR and LVGR expression is dependent on affinity, strand orientation, and the number of Sp1 sites. Swapping the LVGR-proximal high-affinity *SPI-4* with the EVGR-proximal low-affinity *SPI-2* in site strand flipping or inserting an additional *SPI-2* site caused a rearranged NCCR phenotype of increased EVGR expression and faster BKPyV replication. The 5' rapid amplification of cDNA ends revealed an imperfect symmetry between the EVGR- and LVGR-proximal parts of the NCCR, consisting of *TATA* and *TATA*-like elements, initiator elements, and downstream promoter elements. Mutation or deletion of the archetypal LVGR promoter, which is found in activated NCCR variants, abrogated LVGR expression, which could be restored by providing large T antigen (LTag) *in trans*. Thus, whereas Sp1 sites control the initial EVGR-LVGR expression balance, LTag expression can override inactivation of the LVGR promoter and acts as a key driver of LVGR expression independently of the Sp1 sites and core promoter elements.

## IMPORTANCE

*Polyomaviridae* currently comprise more than 70 members, including 13 human polyomaviruses (PyVs), all of which share a bidirectional genome organization mediated by the NCCR, which determines species and host cell specificity, persistence, replication, and virulence. Here, we demonstrate that the BKPyV NCCR is fine-tuned by an imperfect symmetry of core promoter elements centered around *TATA* and *TATA*-like sequences close to the EVGR and LVGR, respectively, which are governed by the directionality and affinity of two Sp1 sites. The data indicated that the BKPyV NCCR is poised toward EVGR expression, which can be readily unlatched by a simple switch affecting Sp1 binding. The resulting LTag, which is the major EVGR protein, drives viral genome replication, renders subsequent LVGR expression independently of archetypal promoter elements, and can overcome enhancer/promoter mutations and deletions. The data are pivotal for understanding how human PyV NCCRs mediate secondary host cell specificity, reactivation, and virulence in their natural hosts.

The *Polyomaviridae* comprise more than 70 polyomavirus (PyV) members, including at least 13 human PyV (HPyV) species (1). HPyV seroprevalence data obtained using the major capsid protein Vp1 as pentamers or virus-like particles indicate that HPyVs infect 50% to 90% of the general human population without known specific signs or symptoms of disease (2–7). As information about the virology and pathology of the 13 human PyVs is only emerging (8, 9), we focused on BK polyomavirus (BKPyV) as a model (10). After primary infection in early childhood, BKPyV persists latently in the renourinary tract with periods of low-level shedding into urine (4, 11, 12). Immunosuppression, which is commonly administered posttransplantation, has been shown to relax the adaptive antiviral immune control (13–16) and to permit high-level replication with median urine BKPyV loads of over 7 log<sub>10</sub> copies/ml that become apparent as decoy cell shedding in urine (15–20). Progression to BKPyV disease is most consistently encountered as nephropathy in 1 to 15% of kidney transplant recipients (21–23) or as hemorrhagic cystitis in 5 to

20% of allogeneic hematopoietic stem cell transplant recipients (24–26).

BKPyV disease involves viral genotypes indistinguishable from those of archetypal BKPyV strains shed asymptotically in the urine of healthy individuals (27–29), arguing that impaired adaptive immune control is necessary and sufficient. However, immu-

nosuppressive drug-specific effects (20, 30) and viral determinants (31, 32) may also contribute to the evolution, kinetics, and severity of disease. At the core of what distinguishes archetype BKPyV strains with a low replicative capacity from the highly replicative strains found in kidney transplant patients are changes in the noncoding control region (NCCR) of the BKPyV genome (33). Akin to all PyVs, the BKPyV NCCR consists of an approximately 400-bp-long sequence which is sandwiched between the early viral gene region (EVGR) and the late viral gene region (LVGR), altogether yielding the double-stranded BKPyV DNA genome of 5,100 bp (34, 35). The NCCR contains *cis*-acting elements coordinating the timing and consecutive steps of EVGR expression, viral genome replication, and LVGR expression (33, 36).

The archetype BKPyV (*ww*) found in the urine of healthy immunocompetent individuals (29, 37, 38) is defined by a linear *ww*-NCCR sequence architecture arbitrarily denoted O<sub>143</sub>, P<sub>68</sub>, Q<sub>39</sub>, R<sub>63</sub>, and S<sub>63</sub> (where the subscript numbers represent the number of nucleotides), which conveys rather slow replication in primary human renal tubular epithelial and urothelial cells (31, 39). In contrast, rearranged NCCRs (*rr*-NCCRs) associated with high blood viral loads and severe renal allograft pathology carry partial duplications and/or deletions of the archetype *ww*-NCCR sequence and give rise to virus strains with elevated levels of EVGR expression, faster viral replication, and more pronounced cytopathic effects in cell culture (31, 32, 40).

Although practically all emerging *rr*-NCCR BKPyV variants appear as unique sequences, we noted some common themes. These consist of an unaltered EVGR-proximal region covering the O<sub>143</sub> block with the origin of replication and the central P<sub>68</sub> block. Insertion strains carry complete or partial duplications of the P<sub>68</sub> block, while deletion strains are characterized by the absence of the LVGR-proximal Q<sub>39</sub> and R<sub>63</sub> blocks and, rarely, the S<sub>63</sub> block (31, 32, 40, 41).

In a detailed point mutational analysis in which more than 28 different transcription factor binding sites (TFBS) were inactivated without altering the overall archetype *ww*-NCCR architecture and length, we identified a hierarchy of TFBS resulting in three phenotypic groups: group 1 TFBS mutations resulted in EVGR activation at the expense of LVGR expression and fast replication rates, similar to the findings for clinical *rr*-NCCR variants. Group 2 TFBS mutations showed an intermediate phenotype with respect to EVGR expression and replication rates, whereas group 3 TFBS mutations reduced both EVGR and LVGR expression and permitted little or no viral replication (32).

Among the various factors, Sp1 appeared to have an outstanding role, since the BKPyV NCCR contained at least three Sp1 sites, two of which appeared to have fundamentally different effects on BKPyV expression and replication. Whereas inactivation of the *Sp1-4* site proximal to the LVGR resulted in strong EVGR expression, inactivation of the *Sp1-2* site proximal to the EVGR abrogated both EVGR and LVGR expression. This effect of the inactivating *sp1-2* mutant also overrode group 1 activation, including the one seen with the *sp1-4* mutant, suggesting a key role of Sp1 in the functionality of the NCCR as a whole.

In the present study, we investigated the role of these two key Sp1 sites and their relationship to core promoter elements in greater detail. Our results demonstrate that the BKPyV NCCR is fine-tuned by an imperfect symmetry of two core promoters with TATA and TATA-like elements at the EVGR and the LVGR, respectively. The bidirectional EVGR and LVGR expression is gov-

erned by the host cell transcription factor Sp1 and involves both DNA strand directionality and binding affinity. The data indicate that the BKPyV NCCR is poised toward EVGR expression, which can be readily discharged by a simple switch in Sp1 binding. The large T antigen (LTag), which is the major EVGR protein product, then drives genome replication and subsequent LVGR expression independently of Sp1 and TATA-like elements, thereby being able to overcome a range of deletions seen in the LVGR promoter of natural BKPyV variants. We discuss the implications of our results as a model for the novel human PyVs and the control of bidirectional gene expression.

## MATERIALS AND METHODS

**Cell culture.** Human primary renal proximal tubule epithelial cells (RPT-ECs; PCS-400-010; ATCC, Manassas, VA, USA) were grown in epithelial cell medium (EpiCM; catalog number 4101; ScienCell Research Laboratory, Carlsbad, CA, USA) supplemented with epithelial cell growth supplement (EpiCGS; catalog number 4152; ScienCell Research Laboratory, Carlsbad, CA, USA) and 2% fetal bovine serum (FBS; catalog number 0010; ScienCell Research Laboratory, Carlsbad, CA, USA). HEK293 cells (CRL1573; ATCC, Manassas, VA, USA), HEK293T cells (CRL3216; ATCC, Manassas, VA, USA), and HEK293TT cells (catalog number 0508000; NCI-Frederick Repository Service, Frederick, MD, USA) were propagated in Dulbecco's modified Eagle's medium (DMEM), high-glucose formulation (DMEM-H; catalog number D5671; Sigma-Aldrich, St. Louis, MO, USA), containing 8% FBS (catalog number S0113; Biochrome AG, Berlin, Germany). Medium for cultivation of HEK293TT cells was supplemented with 400 µg/ml hygromycin B (Calbiochem, San Diego, CA, USA). COS-7 cells (CRL1651; ATCC, Manassas, VA, USA) were grown in DMEM-H, containing 5% FBS. All cultures were supplemented with 2 mM L-glutamine (catalog number K0302; Biochrome AG, Berlin, Germany).

**FACS-based, bidirectional reporter assay.** The bidirectional reporter construct used to measure expression of the early (red fluorescent protein [RFP]) and late (green fluorescent protein [GFP]) virus gene regions has been described before (31). Furthermore, we described a fluorescence-activated cell sorter (FACS)-based quantification method for this reporter construct (32). While the use of flow cytometry for the reporter assay enables a convenient means of visualization of expression, at the same time, accurate and reproducible quantification is achieved. In particular, the gating for the same number of transfected cells from each sample as a method of normalization overcomes the problem of different transfection efficiencies between different plasmid preparations, mutants, or cell lines. HEK293, HEK293T, or HEK293TT cells were seeded in 12-well plates and transfected at 70 to 80% confluence with the Lipofectamine 2000 reagent (catalog number 11668-019; Invitrogen, Carlsbad, CA) at a ratio of 3:1 (3 µl reagent, 1 µg plasmid DNA) in Opti-MEM medium (Gibco, Grand Island, NY, USA) according to the manufacturer's instructions. Medium was replaced with DMEM-H+10% FBS on the next morning. At 48 h posttransfection, the cells were rinsed once with phosphate-buffered saline (PBS)-2.5 mM EDTA and then detached, suspended, and transferred to 5-ml polystyrene round-bottom FACS tubes (BD, Franklin Lakes, NJ, USA) with DMEM (without phenol red) and 1% fetal calf serum (FCS). Directly before each measurement, DAPI (4',6-diamidino-2-phenylindole; catalog number D8417; Sigma-Aldrich, St. Louis, MO, USA) was added (final concentration, 1 ng/ml) as a dead cell marker, and the cells were resuspended. FACS measurements were carried out on a Fortessa cytometer (BD, Franklin Lakes, NJ, USA). For GFP, excitation was at 488 nm (blue laser) and emission was at 530/30 nm; for RFP, excitation was at 561 nm (yellow-green laser) and emission was at 586/15 nm; and for DAPI, excitation was at 405 nm (violet laser) emission was at 450/50 nm. In order to calculate the weighted mean fluorescence intensity (MFI) for red (early) and green (late) expression, the cell number (*N*) and mean fluorescence (*I*) of quadrants Q1 (red cells), Q2 (red and green cells), and

Q4 (green cells) were inserted into the following formulas: MFI (red) =  $[(N_{Q1} \cdot I_{Q1}) + (N_{Q2} \cdot I_{Q2})]/(N_{Q1} + N_{Q2} + N_{Q4})$  and MFI (green) =  $[(N_{Q2} \cdot I_{Q2}) + (N_{Q4} \cdot I_{Q4})]/(N_{Q1} + N_{Q2} + N_{Q4})$ .

The early expression of all constructs was normalized to that of the Dunlop strain (set as 100%), and late expression was normalized to that of the archetype *ww(1.4)* strain (set as 100%). The mean values and standard deviations were calculated with GraphPad Prism software (version 6 for Mac OS).

**EMSA.** Electrophoretic mobility shift assay (EMSA) analysis of TFBS was performed as described previously (42). Briefly, 10  $\mu$ g of nuclear extract from RPTECs was mixed with binding buffer (20 mM PIPES [piperazine-*N,N'*-bis(2-ethanesulfonic acid)], pH 6.8; 50 mM NaCl; 1 mM dithiothreitol [DTT]; 0.25 mg/ml bovine serum albumin; 100  $\mu$ M ZnSO<sub>4</sub>; 0.05% NP-40; 4% Ficoll) and approximately 5 fmol of <sup>32</sup>P-labeled, duplexed oligonucleotide in a final volume of 20  $\mu$ l. The oligonucleotides with the *SP1-2* and *SP1-4* binding sites were described before (32). Nuclear extracts were prepared as described by Schreiber et al. (43) by scraping cells with ice-cold PBS off 10-cm dishes and collecting them in Eppendorf tubes. After centrifugation they were swollen in hypotonic buffer (10 mM HEPES, pH 7.9; 10 mM KCl; 0.1 mM EDTA; 2.5 mM DTT) and lysed by addition of NP-40 (final concentration, 0.5%). After centrifugation of the nuclei, proteins were extracted in nuclear extract buffer (20 mM HEPES, pH 7.9; 25% glycerol; 400 mM NaCl; 1 mM EDTA; 2.5 mM DTT). Competing, unlabeled oligonucleotides were used as described in the legend to Fig. 2. After incubating the mixture on ice for 30 min, samples were separated on a native 4% polyacrylamide gel with 0.25× TBE (Tris-borate-EDTA) as the running buffer. The detection of  $\beta$  decay was carried out with a Fujifilm FLA-7000 image plate reader.

**ChIP.** Chromatin immunoprecipitation (ChIP) was performed according to the manufacturer's instructions (Magnify chromatin immunoprecipitation system; Life Technologies/Thermo Fisher Science). Briefly, HEK293TT cells were transfected in 10-cm dishes with the BkPyV *ww* reporter construct and incubated for 48 h. The chromatin was cross-linked directly in the dish for 10 min with 10% formaldehyde. The cross-linking was quenched with 0.5 M glycine solution. Cells were harvested with ice-cold PBS, collected by centrifugation, and lysed. For the chromatin fragmentation, lysates were treated with micrococcal nuclease (20 min at 37°C; NEB) and sonicated with 30 cycles of 30-s pulses and 30 s of cooling in between each pulse (Sonicator Q700; QSonica). The ChIP antibodies were Sp1 D4C3 (ChIP-validated rabbit monoclonal antibody; Cell Signaling) (44) and a rabbit control antibody included with the kit. For PCR analysis by HotStar *Taq* (Qiagen) and a quantitative PCR (qPCR) SYBR green assay (PowerUp SYBR green; Thermo Fisher Scientific), the following primers were validated and used: primer NCCR-f (TCAGAAAAGCCTCCACACC) and primer NCCR-r (CTTTGGCCA GTTCCACTTC). qPCR data were analyzed by the  $\Delta\Delta C_T$  threshold cycle ( $C_T$ ) method as described before using *ww*-NCCR input and background control ChIP for normalization.

**5' RACE analysis of early and late transcripts.** To characterize the 5' ends of viral transcripts and, hence, to identify the transcription start sites, we performed 5' rapid amplification of cDNA ends (5' RACE) procedures according to the manufacturer's instructions (5' RACE system for rapid amplification of cDNA ends; Invitrogen/Thermo Fisher Scientific). Briefly, we isolated total RNA from RPTECs (RNeasy minikit; Qiagen) which were infected with either archetype virus or the Dunlop strain and reverse transcribed the mRNA by using a mixture of random hexamers and oligo(dT) primers (SuperScript II; Invitrogen/Thermo Fisher Scientific). The resulting cDNAs of viral origin were specifically amplified by using the following gene-specific primers (GSP): sTag-GSP1 (5'-AAGGG CAGTGCACAGAAG-3'), sTag/LTag (5'-AATCAGGCTGATGAGCTAC C-3'), LTag-GSP1 (5'-TCTTCAGGCTCTTCTGG-3'), LTag-GSP2 (5'-T GGTGTGKAGTGTGAGA-3'), agno-GSP1 (5'-TACAGCAGGTAAG CAGTG-3'), agno-GSP2 (5'-TCCCGTCTACACTGTCTT-3'), VP2-GSP1 (5'-TGATAGAGGCCTACAGTG-3'), VP1-GSP1 (5'-AAGGCCT

CTCCACTGTG-3'), and VP1-GSP2 (5'-CCAGCACTCAACTGGATA AG-3').

**In silico analysis of the BkPyV NCCR.** To search for potential transcription factor binding sites within the BkPyV NCCR and to evaluate the effect of mutations on the binding sites, we used the MatInspector software tool (Genomatix, Munich, Germany). Additionally, to analyze the presence of core promoter elements, we used the search tool Element (http://lifefaculty.biu.ac.il/gershon-tamar/index.php/resources) (45).

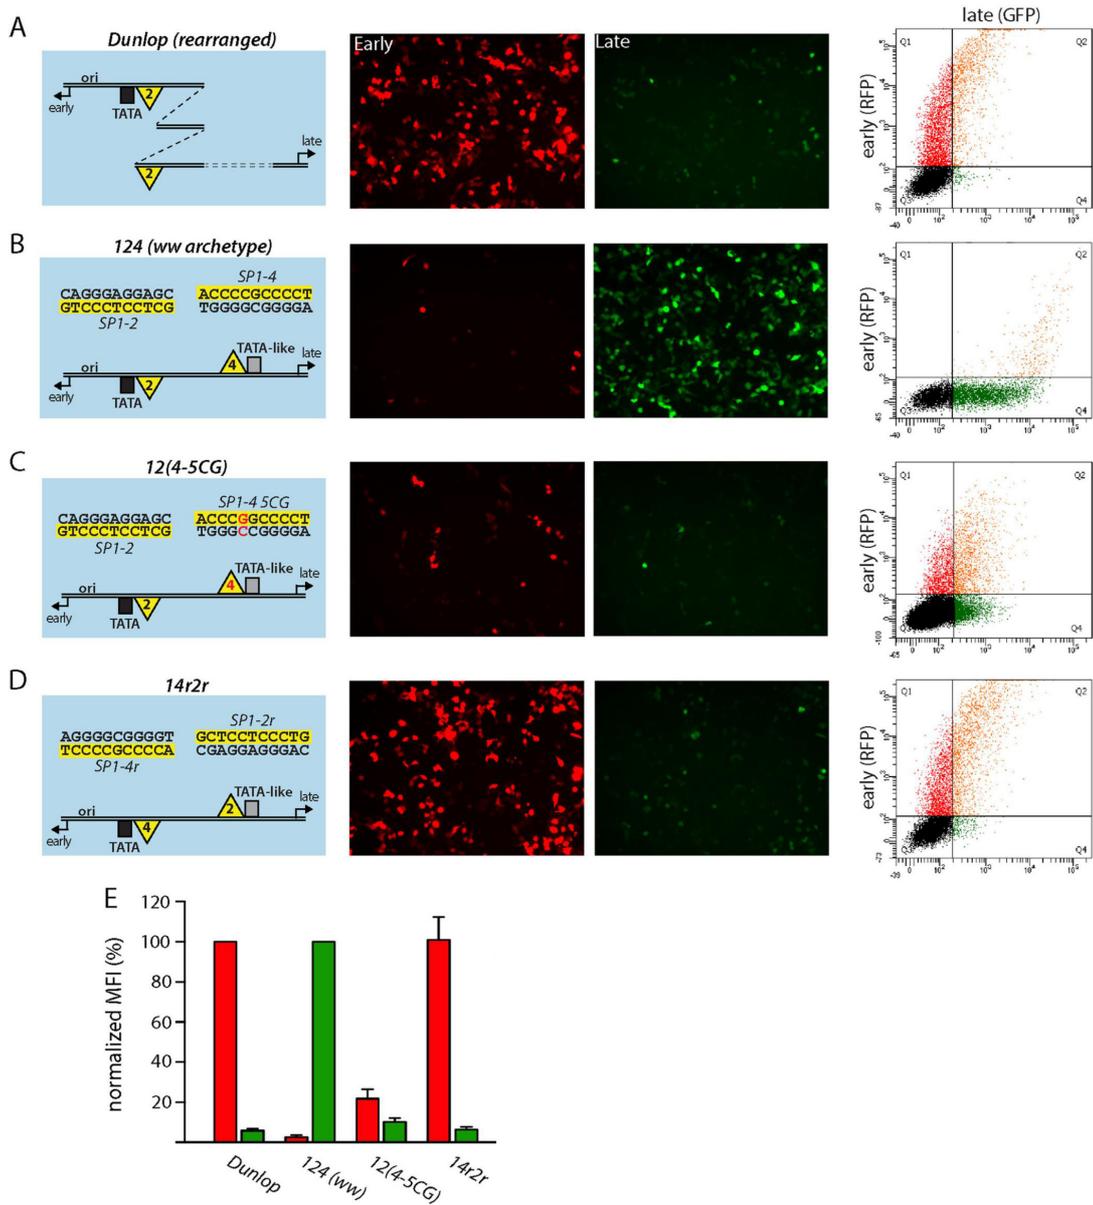

**Transfection of BkPyV genome into COS-7 cells and infection of RPTECs.** Transfection of BkPyV genomes into cells was initiated by cutting BkPyV plasmid DNA with BamHI and religating the diluted DNA as described previously (46). Transfection of religated BkPyV genomic DNA into COS-7 cells was performed when the cells were at 90 to 95% confluence in 6-well plates using Lipofectamine 2000 (catalog number 11668-019; Invitrogen, Carlsbad, CA, USA) at a reagent/DNA ratio of 3:1 according to the manufacturer's instructions. At 6 h after transfection, the medium was replaced with DMEM-H containing 5% FCS. At 7 days post-transfection, COS-7 cell supernatants were harvested and the number of DNase-protected genomic equivalents (GEq) per milliliter was quantified by quantitative reverse transcription-PCR (see the next paragraph). For the infection of RPTECs with COS-7 cell supernatants, cells were seeded at 75,000 cells per well of a 24-well plate in 0.5 ml of supplemented EpiCM. After 24 h, when the cells were at a confluence of approximately 50%, RPTECs were exposed to 200  $\mu$ l of the corresponding virus preparations adjusted to  $2 \times 10^7$  GEq for each construct at 37°C for 2 h, followed by removal, washing, and replacement with EpiCM supplemented with 0.5% FCS.

**BkPyV viral loads by real-time PCR.** BkPyV loads were quantified after DNA extraction from 200- $\mu$ l cell culture supernatants with a QIAamp DNA blood minikit (Qiagen, Hombrechtikon, Switzerland). The real-time PCR protocol for detection of BkPyV DNA samples targets the BkPyV large T antigen-coding sequence and has been described before (47).

**Western blotting.** Lysis of HEK293, HEK293T, and HEK293TT cells was done in NP-40 buffer (50 mM Tris-HCl, pH 8.0; 150 mM NaCl; 1% NP-40; 1× protease inhibitors [Roche]). Equal volumes of cell lysates, adjusted to 10  $\mu$ g total protein, were separated by SDS-PAGE and electrotransferred onto a 0.45- $\mu$ m-pore-size polyvinylidene difluoride membrane (catalog number IPFL00010; Millipore/Merck, Darmstadt, Germany). The membrane was blocked with Odyssey blocking buffer (catalog number 927-40000; LI-COR, Lincoln, NE, USA) diluted 1:2 in Tris-buffered saline (TBS). The membrane was then incubated with the following primary antibodies: polyclonal rabbit anti-LTag (1:10,000; C. H. Rinaldo, University of North Norway, Tromsø, Norway) and monoclonal mouse antiactin (1:5,000; Abcam, Cambridge, England) in Odyssey blocking buffer. After washing 5 times with TBS-0.1% Tween 20, the membrane was incubated in the following secondary antibodies: goat anti-rabbit immunoglobulin antibody conjugated with IRDye 800CW (1:10,000; catalog number 926-32211; LI-COR) and donkey anti-mouse immunoglobulin antibody conjugated with Alexa Fluor 680 (1:15,000; catalog number A10038; Invitrogen). Protein detection and quantification were done with a LI-COR Odyssey CLX system.

## RESULTS

**Swapping of Sp1 sites within the NCCR causes rearrangement-like activation of EVGR expression.** To measure the early and late promoter activity of the BkPyV NCCR, we transfected a bidirectional reporter construct into human embryonic kidney HEK293 cells, which allows monitoring of EVGR expression by the red fluorescence of DsRed and monitoring of LVGR expression by the green fluorescence of enhanced green fluorescent protein (31, 32). Using this reporter assay, the strain Dunlop NCCR, as a representative of *rr*-NCCRs bearing duplications and deletions, showed strong EVGR expression (red) but only a low level of LVGR expression (green) (Fig. 1A). The Dunlop NCCR contains an intact

**FIG 1** Swapping of *SPI-2* and *SPI-4* in the BKPyV NCCR affects early and late promoter activity similarly to major rearrangements. (A to D) (Left) Schematic representation of NCCRs tested with the FACS-based, bidirectional reporter assay. All NCCRs were cloned into the previously described reporter vector pHRG, in which RFP serves as a marker for early expression and GFP serves as a marker for late expression (31). The Gardner isolate-derived laboratory strain Dunlop is characterized by triplication of the P-block sequences and deletion of Q- and R-block sequences. The BKPyV archetype NCCR *124* is used as a reference. Horizontal black lines, double-stranded DNA of the NCCR; black box, conserved TATA box; gray box, TATA-like element; yellow triangles labeled 2, *SPI-2* Sp1 transcription factor binding site; yellow triangles labeled 4, *SPI-4* Sp1 transcription factor binding site; black number 4, Sp1-binding site with archetype sequence; red number 4, Sp1-binding site carrying one or more mutations; yellow highlight, the respective Sp1 upper-strand sequence with respect to the direction of early and late transcription (black arrows). (Middle two columns) The indicated NCCR reporter constructs were transfected into HEK293 cells, and fluorescence images for RFP (early) and GFP (late) expression were taken at 2 days posttransfection. (Right) Representative flow cytometry measurements of the indicated NCCRs. x axis, GFP fluorescence; y axis, RFP fluorescence. For each measurement, we gated for 5,000 transfected (fluorescent) cells in quadrants Q1, Q2, and Q4. (E) For quantification, the normalized MFI (in percent) was calculated as described in Materials and Methods. Early expression was normalized to that of strain Dunlop (red MFI = 100%), and late expression was normalized to that of NCCR *124* (ww archetype) (green MFI = 100%). Quantification results are from at least 3 independent replicates.

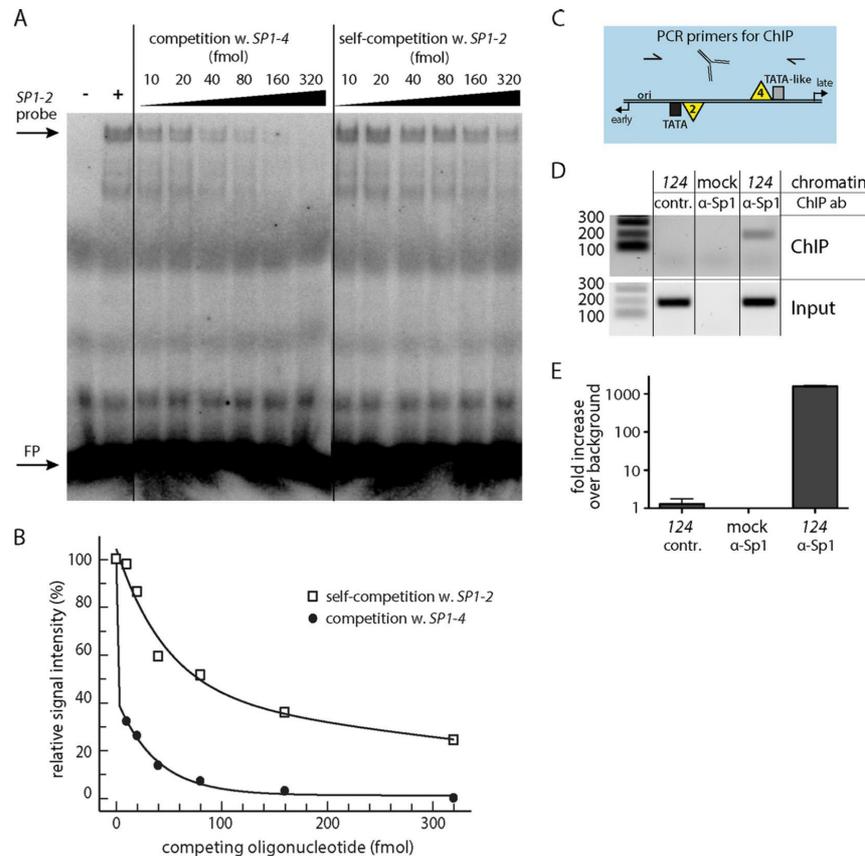

*SPI-2* site upstream of the TATA box but bears two incomplete duplications of the P block, adding one *SPI-2* site at a more distant upstream location, while LVGR proximal sequences, including *SPI-4*, are deleted (Fig. 1A, left, with the yellow triangles labeled 2 indicating *SPI-2*). In contrast, the archetype BKPyV *ww* strain has all three Sp1 sites in the archetype position (*ww*-NCCR 124) and showed a low level of EVGR expression (red) but strong LVGR expression (green) (Fig. 1B, left, *ww* archetype NCCR 124, with the yellow triangles labeled 2 and 4 indicating *SPI-2* and *SPI-4*, respectively). As reported previously (32), point mutations, like the naturally occurring *SPI-4* variant 5CG (which has a C-to-G transition at position 5) from a patient with BKPyV-associated hemorrhagic cystitis (48), are sufficient to cause an activation of EVGR expression compared to the archetype *ww*-NCCR, at the expense of LVGR expression [NCCR 12(4-5CG) in Fig. 1C and E]. Given the striking effects of rather subtle Sp1 site mutations with respect to EVGR and LVGR expression (32), we investigated whether or not the different Sp1 sites might have different sequence-encoded properties. We noted that *SPI-2* and *SPI-4* have inverse orientations relative to one another, which is possible because Sp1 sites are composed of nonpalindromic sequences. In a first approach, the early *SPI-2* site and the late *SPI-4* site were simply swapped and placed in reverse orientation to maintain the archetypal strand orientation, yielding NCCR 14*r*2*r* (where the letters *r* indicate inverted *SPI-4* and *SPI-2* sequences, respectively) (Fig. 1D and E; the C-rich sequence of the EVGR-proximal Sp1 site and the C-rich sequence of the LVGR-proximal Sp1 site are highlighted in yellow). Compared to the archetype, NCCR 14*r*2*r* caused a strong increase of EVGR expression and decreased LVGR, similar to the phenotype produced by the *rr*-NCCR of the Dunlop strain (Fig. 1A, D, and E). Quantification using the mean fluorescence intensities (MFI) demonstrated that the increase in EVGR expression corresponded to 80 to 100% of the Dunlop NCCR signals (Fig. 1E). At the same time, the level of LVGR expression was reduced to about 10% of the archetype level. We concluded that maintenance of the Sp1 sites but simple swapping of *SPI-2* and *SPI-4* within the archetypal NCCR was sufficient to invert the bidirectional expression pattern of the archetype promoter/enhancer system.

**The LVGR *SPI-4* has a higher *in vitro* Sp1-binding affinity than the EVGR *SPI-2*.** Although Sp1 has been shown to bind to both *SPI-2* and *SPI-4* *in vitro* (32), there are differences in the respective sequence compositions. While *SPI-4* represents a perfect Sp1 consensus sequence, *SPI-2* carries deviations by A/T base pairs (Fig. 1B to D, sequences indicated in yellow). To examine whether the sequence differences were associated with different binding affinities, an EMSA-based competition assay was employed. <sup>32</sup>P-radiolabeled, duplexed oligonucleotides carrying *SPI-2* were incubated with nuclear extract from primary human renal proximal tubule epithelial cells (RPTECs) and mixed with increasing concentrations of unlabeled oligonucleotides containing *SPI-2* or *SPI-4* (Fig. 2A). As shown, competition with the unlabeled *SPI-4* oligonucleotides decreased the EMSA signal more readily than competition with the unlabeled *SPI-2* oligonucleotides: while 10 fmol of the *SPI-4* oligonucleotide was enough to reduce the *SPI-2* signal to about 30% of the signal for the archetype, self-competition required approximately 30 times higher competitor concentrations (Fig. 2B). This finding indicates that the *SPI-4* binding site has a higher affinity for Sp1 binding than *SPI-2*, as expected from comparison of their sequences with the

perfect Sp1 consensus sequence. Together, the combined data suggest that the affinity of Sp1 binding to the intact local *SPI-2* and *SPI-4* sites determined the higher activity of the LVGR promoter in the archetype *ww*-NCCR. To complement the *in vitro* data, a chromatin immunoprecipitation (ChIP) assay was performed in *ww*-NCCR reporter construct-transfected cells (Fig. 2C and D). ChIP with the Sp1 antibody yielded an enrichment of about 1,600-fold compared to that achieved with a control antibody, demonstrating the strong binding of Sp1 to the BKPyV NCCR *in vivo* (Fig. 2E).

**Strand inversion of Sp1 sites disrupts the archetype EVGR-LVGR expression balance.** To examine the potential contributions of the nonpalindromic Sp1 sites to the directionality of gene expression, *SPI-2* and *SPI-4* were flipped in place, yielding the NCCRs 12*r*4*r*, 12*r*4, and 12*r*4*r*, as well as swapped with respect to their original archetype position (NCCR 142) (Fig. 3A to D). All NCCR inversion mutants showed impaired LVGR expression with a reduction in the level of expression to about 20% of the archetype level. Of note, all of these constructs except 142 still carried an intact high-affinity *SPI-4* site in the LVGR promoter region, including NCCR 12*r*4, in which *SPI-4* was even maintained in its original strand orientation (Fig. 3B and E). At the same time, all inversion mutants showed a moderate level of EVGR activation compared to the archetype, whereby the NCCR 12*r*4 had the strongest expression in the range of 25% of the level seen for the Dunlop *rr*-NCCR. These observations indicate that the relative Sp1 site orientation was critical for regulating bidirectional expression, in addition to affinity. Importantly, the Sp1 sites were able to convey an orientation-dependent directionality that seemed to be functionally as important as the local Sp1-binding affinity or deletion of *SPI-4*. Interestingly, NCCR 142 yielded a high EVGR expression level similar to that of Dunlop and the initially tested 14*r*2*r* mutant (Fig. 3D and E and 1D and E). We concluded that, when placing the high-affinity *SPI-4* site in the proximity of the EVGR, its orientation relative to the remaining NCCR did not matter anymore. This notion was further corroborated by another set of mutants, where the low-affinity *SPI-2* was replaced with the high-affinity *SPI-4*, such that the EVGR and LVGR proximal positions contained Sp1 sites with equal affinities in all possible combinations of site orientations (Fig. 3F to J, NCCRs 14*r*4, 14*r*4*r*, 144, and 144*r*). All of the resulting mutants showed an equally high level of EVGR expression in the range of 80% of that of strain Dunlop, coupled to a profound loss of LVGR expression. Thus, a high-affinity Sp1 site in the proximity of the EVGR provided a strong activation, which in no case permitted rescue of the archetype expression pattern by an Sp1 site in an LVGR of similar sequence, affinity, or orientation (Fig. 3J). Conversely, the data further support the notion that the bidirectional fine-tuning of NCCR expression depends on the modulation of Sp1 affinity at the EVGR site.

**Early promoter activity correlates with the Sp1-binding affinity of the early Sp1 site.** To examine the role of Sp1 affinity in the critical EVGR position, the mutant 14*r*4 was used for further study by introducing point mutations that had been identified in patient variants (48) and previously shown by us to lower the Sp1-binding affinity (32). By slightly lowering the affinity of the EVGR-proximal Sp1 site with the mutant 1(4*r*-10CT)4 (where 10CT indicates the exchange of C to T in position 10), the expression of EVGR decreased to about half the level seen for mutant 14*r*4 (or 30 to 50% of that for the Dunlop reference strain) (Fig. 4B

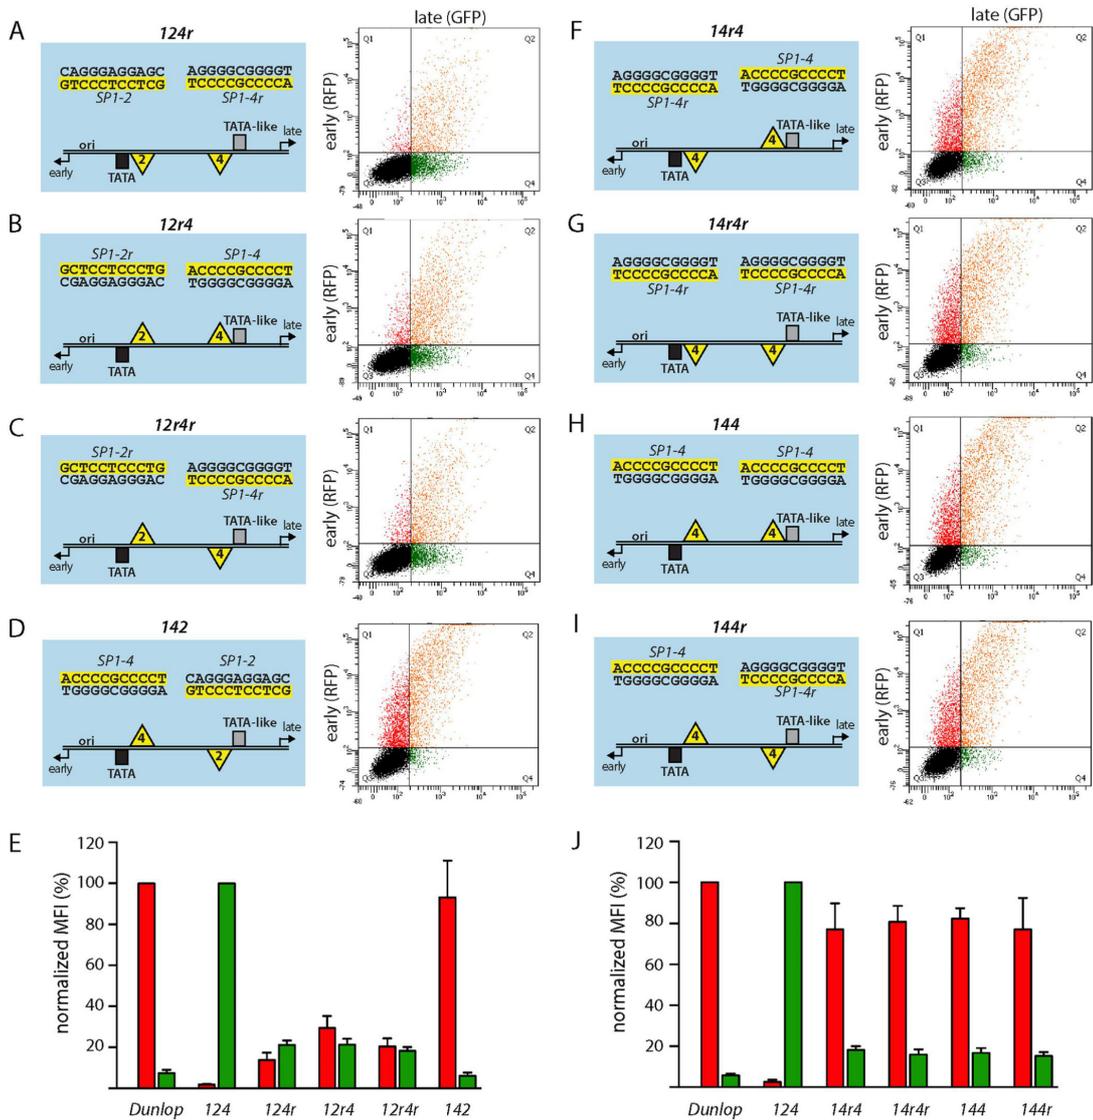

**FIG 2** *SP1-2* and *SP1-4* differ in Sp1 affinity in EMSA competition assays. (A) Representative EMSA result after competition of the radiolabeled *SP1-2* probe with (w.) unlabeled *SP1-4* or unlabeled *SP1-2* (self-competition) at the indicated concentrations. Lane -, binding mix without nuclear extract; lane +, binding mix without competition; FP, free probe. (B) Plot of quantitative readout of EMSA signals. x axis, concentration of competing oligonucleotide; y axis, signal strength relative to that of the uncompleted *SP1-2* signal, set to 100%. (C) Scheme of NCCR with primer binding sites for ChIP assay. (D) Semiquantitative analysis of ChIP assay results by agarose gel electrophoresis. Mock, untransfected HEK293TT cells; contr., ChIP with rabbit negative-control antibody (ab) supplied with the kit. Numbers on the left are denote DNA fragment sizes (in base pairs). (E) Quantification of ChIP assay result by qPCR with SYBR green. Calculation was carried out by  $\Delta\Delta C_T$  method (with normalization to the *ww*-NCCR input and the background control).

and F). The intermediate-affinity mutant *1(4r-5CG)4* allowed approximately 15% of the level of *14r4* EVGR expression (10% of that of Dunlop), while the double mutant showed only 5% of the level of expression by Dunlop (a >75% reduction compared to that for the *14r4* mutant) (Fig. 4C, D, and F). In contrast to the gradual decrease in the level of EVGR expression, the late promoter activity remained at the same low level (about 20% of the archetype level of expression). Hence, just lowering the affinity of the EVGR-proximal Sp1 site was not sufficient to restore a high level of LVGR expression. The data suggest that, in addition to affinity, particularities of the *SP1-2* sequence might play a role for achieving a high level of LVGR activity.

To confirm the mechanistic relevance of these findings, the NCCR mutants were placed into a BKPyV Dunlop backbone and analyzed in a viral replication assay. To minimize potential

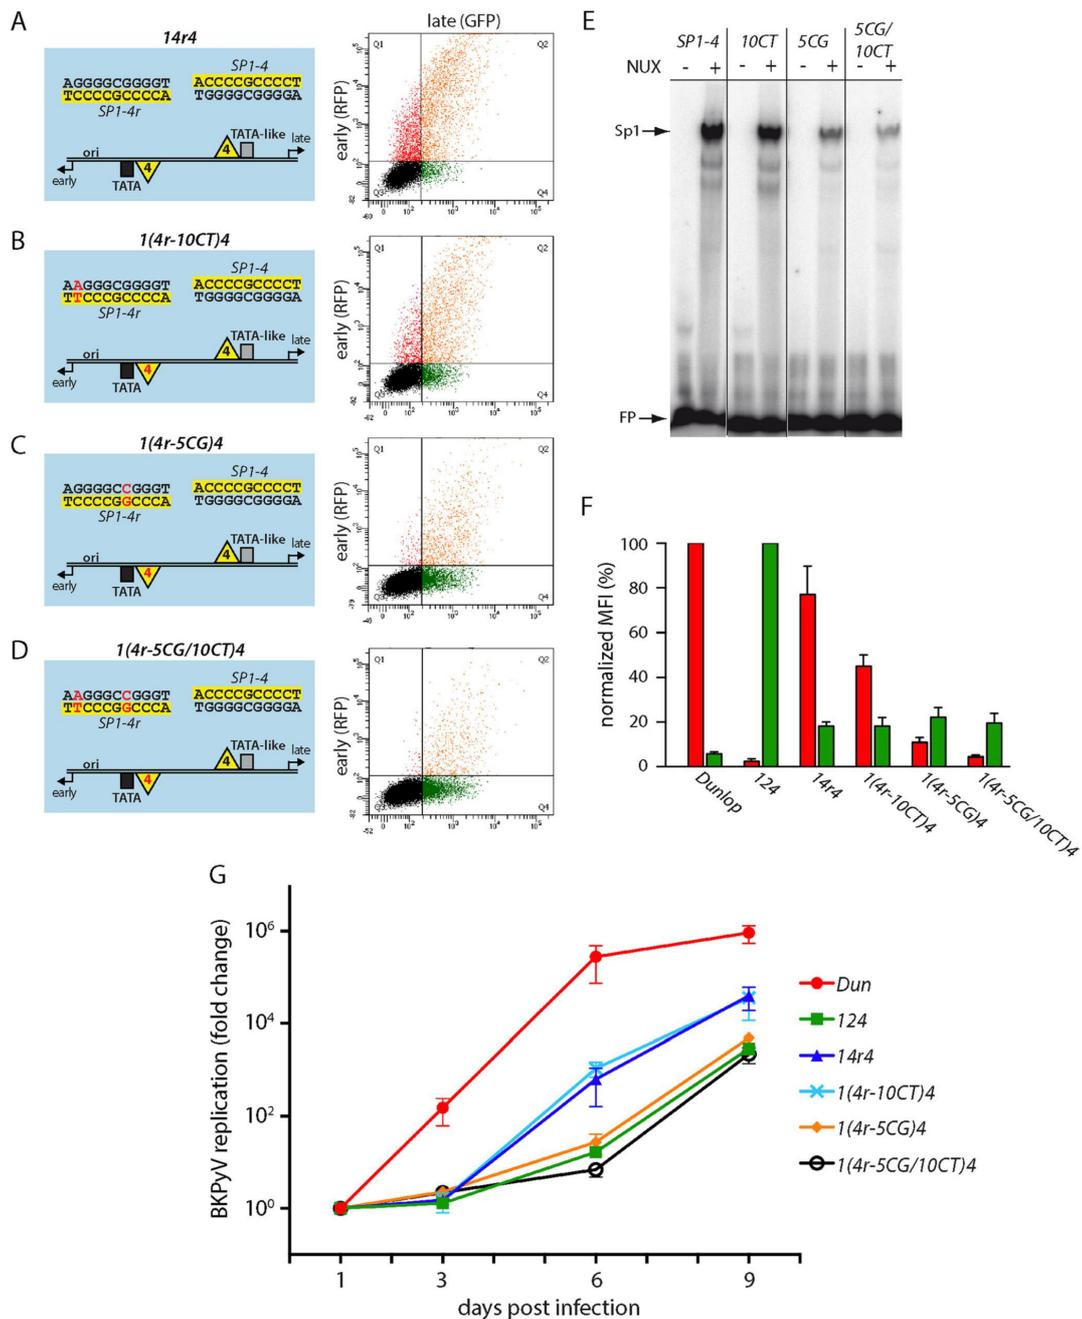

effects of EVGR expression and, hence, LTag levels, infectious supernatants were generated in COS-7 cells constitutively expressing simian virus 40 (SV40) LTag, as reported previously (32), and were used to infect RPTECs. Supernatants from RPTECs were then taken at 1, 3, 6, and 9 days postinfection (dpi), and viral loads were quantified by qPCR (Fig. 4G). As expected, the Dunlop strain had the highest replication rate of the tested strains, reaching supernatant viral loads of more than  $10^{10}$  genome equivalents (GEq)/ml at 6 dpi, which corresponded to a more than 200,000-fold increase compared to the input (1 dpi). Importantly, the recombinant virus strains *14r4* and *1(4r-10CT)4* were functional and showed accelerated replication compared to that of the archetype virus, reaching levels of replication 1,000-fold that of the archetype virus at 6 dpi and about 40,000-fold that of the archetype virus at 9 dpi, respec-

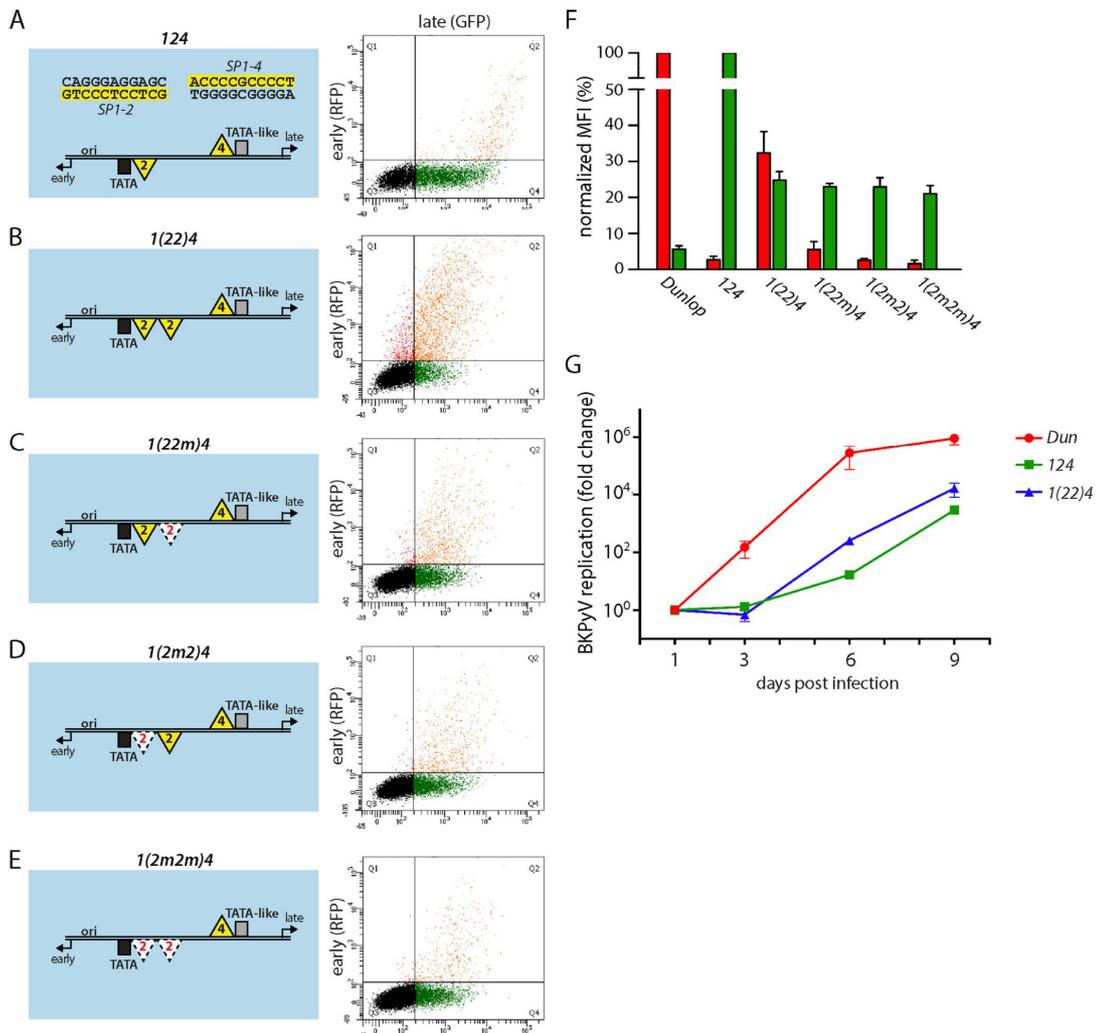

**FIG 3** Position, orientation, and affinity of Sp1 sites determine the directionality of EVGR and LVGR expression. (A to D) (Left) Schematic representation of NCCRs tested with the FACS-based, bidirectional reporter assay in HEK293 cells. All mutant NCCRs have the length and architecture of the BkPyV archetype NCCR 124 but carry inverted Sp1 sites, as indicated with the letter *r* (e.g., NCCR 124*r* has an inverted SP1-4 sequence). (Right) Representative flow cytometry measurements are shown next to the schematic representations, which are described in the legend to Fig. 1. (E) Quantification of the constructs listed in panels A to D using the normalized MFI from at least 3 independent replicates, as described in the legend to Fig. 1. (F to I) Schematic representation of NCCRs, where the archetype SP1-2 was replaced with the sequence of the high-affinity SP1-4. (J) Quantification of the constructs listed in panels F to I using the normalized MFI from at least 3 independent replicates, as described in the legend to Fig. 1.

tively. However, the weakened affinity in the *I*(4*r*-10CT)*4* strain seen in the reporter assay did not translate into measurable differences in replication kinetics, suggesting that the EVGR-proximal Sp1 affinity was still strong enough to drive

EVGR expression in the context of viral infection in cell culture. In contrast, the viruses carrying the stronger mutations *I*(4*r*-5CG)*4* and *I*(4*r*-5CG/10CT)*4* did not seem to allow rapid viral replication (Fig. 4G). Thus, the data indicate that the Sp1

**FIG 4** Lowering of the Sp1 affinity in the EVGR-proximal position of NCCR *14r4* reduces EVGR expression and viral replication. (A to D) Schematic representation (left) and representative FACS plot (right) of the indicated NCCRs tested in the bidirectional reporter assay in HEK293 cells. The numbering of the point mutants is relative to the first position of the *SP1-4* site in the archetype orientation [e.g., NCCR *1(4r-10CT)4* contains the exchange of C to T in position 10, while the late *SP1-4* site is unaltered]. (E) EMSA analysis of binding affinity in the absence and presence of nuclear extracts (NUX) confirms that the inserted point mutations lower the *in vitro* affinity of the respective variants. (F) Quantification of the constructs listed in panels A to D using the normalized MFI from at least 3 independent replicates, as described in the legend to Fig. 1. (G) Mutant BKPvY replication in primary human RPTECs using infectious supernatants generated by transfection of COS-7 cells. The cell culture supernatants were taken at 1, 3, 6, and 9 days postinfection (x axis), and DNase-protected viral loads were quantified by qPCR. Results were normalized to the amount of input virus (day 1) and are shown as the fold change (y axis). Dun, strain Dunlop.

**FIG 5** Addition of a second low-affinity *SP1*-2 site increases the level of EVGR expression. (A to E) The indicated mutant NCCRs inserted into the bidirectional reporter constructs (left) were transfected into HEK293 cells, and representative FACS plots are shown (right). (F) Quantification of the constructs listed in panels A to E using the normalized MFI from at least 3 independent replicates, as described in the legend to Fig. 1. Note that the y axis was divided for better visibility of the low range. (G) Mutant BKPyV replication in primary human RPTECs using infectious supernatants generated by transfection of COS-7 cells. Cell culture supernatant was taken at 1, 3, 6, and 9 days postinfection (x axis), and DNase-protected viral loads were quantified by qPCR. Results were normalized to the amount of input virus (day 1) and are shown as the fold change (y axis).

affinity of the EVGR-proximal site was also reflected in the level of BKPyV replication, although the infection assay did not achieve the same nuanced resolution observed by the flow cytometry assay interrogating the bidirectional reporter constructs.

**EVGR expression can be enhanced by low-affinity Sp1 site duplication.** Given the frequently observed duplications in the vicinity of the EVGR of rearranged NCCRs, including one of the

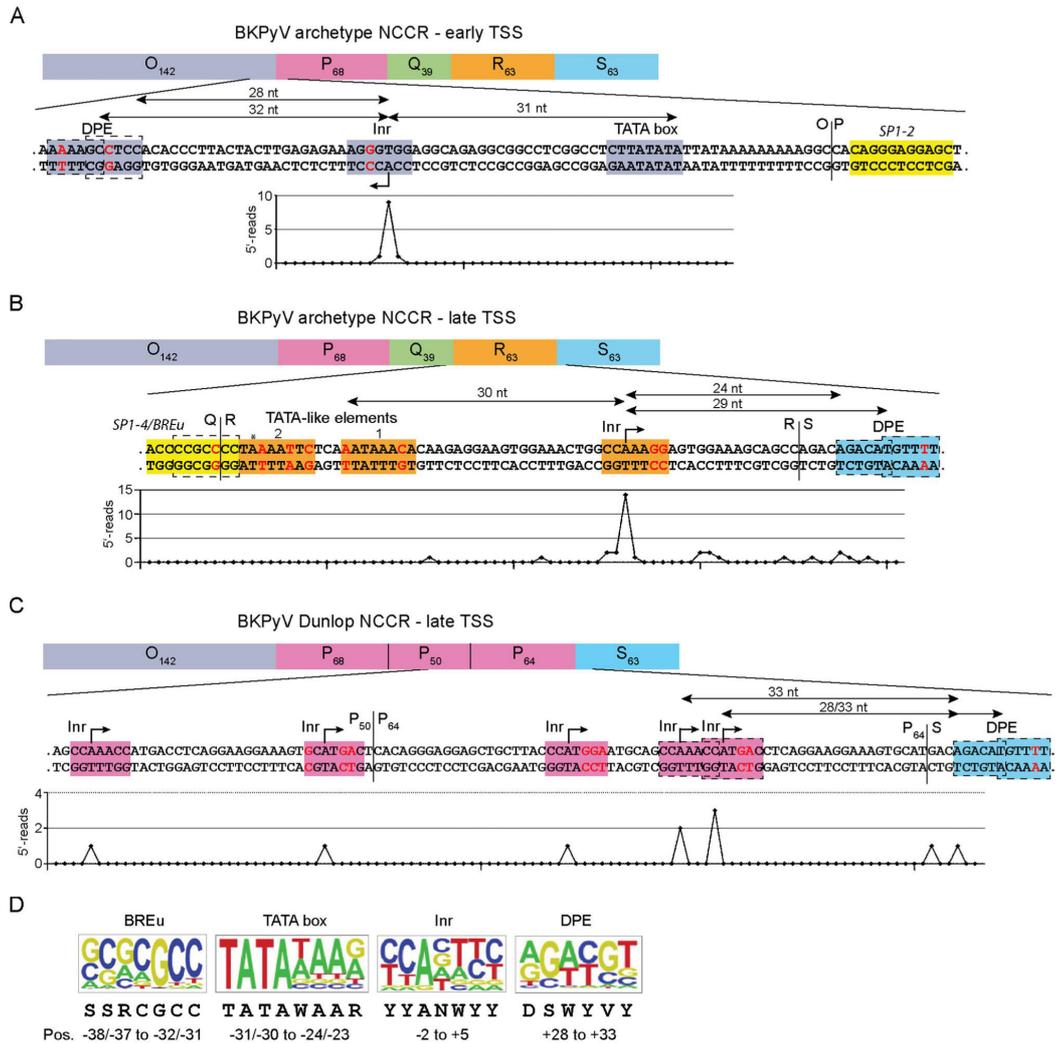

NCCRs of the Dunlop strain, we examined expression in another set of NCCR mutants which carried a second *SP1*-2 site in the EVGR-proximal position, NCCR 1(22)4 (Fig. 5A and B). This additional binding site was sufficient to increase the level of EVGR expression 15-fold compared to that for the archetype, reaching about 30% of the level for Dunlop (Fig. 5F). To exclude a potential distance or length effect, we also examined inactivated Sp1 sites yielding the NCCRs 1(22m)4, 1(2m)4, and 1(2m2m)4, in which

the proximal *SPI-2* site, the distal *SPI-2* site, or both *SPI-2* sites were mutated to sequences that no longer bound Sp1 (Fig. 5C, D, and E). These additional NCCR mutants showed reduced EVGR expression compared to the *I(22)4* mutant, in line with the notion that Sp1 binding and not any inserted sequence mediated an elevated level of EVGR expression. Together, these findings confirm that *SPI-2* duplications found in parts of the P block of some patient isolates (31) as well as the Dunlop strain contribute to activation of the EVGR phenotype. Interestingly, all the experimentally designed insertions of the low-affinity *SPI-2* diminished LVGR expression to a similar degree, again suggesting that some additional factors in the NCCR sequence might play a role. In the viral replication assay, recombinant BKPyV bearing NCCR *I(22)4* propagated slightly faster than the archetype NCCR *124* virus, which is in line with the results of the bidirectional reporter assay (Fig. 5G).

**Characterizing the early and late core promoter elements of the archetype NCCR.** Given the strong effects of Sp1 sites on EVGR and LVGR expression through position, orientation, and affinity, we addressed potential cooperating components in their close proximity. Analysis of the NCCR sequence in the vicinity of the *SPI-2* and the *SPI-4* sites identified a canonical *TATA* box upstream of the EVGR start codon but only potential *TATA*-like elements upstream of the LVGR start codon which deviated from a perfect *TATA* box by several mismatches (49). The actual transcriptional start site (TSS) for the BKPyV NCCR EVGR was derived by 5' rapid amplification of cDNA ends (5'-RACE) analysis (Fig. 6A), which also revealed a sequence consistent with loci of initiator elements (*Inr*) (Fig. 6A). The positions of the *Inr* elements allowed the deduction of other core promoter elements (CPEs), which were located within the canonical distances upstream and downstream of the identified TSSs. The web-based search tool ElemeNT (45) confirmed the position of the early core promoter, which is located close to the O-block-P-block boundary and which is defined by the conserved *TATA* box and by a prominent *Inr* 31 bp downstream (Fig. 6A). In addition, a downstream promoter element (DPE) was identified at the typical distance of 28 to 32 nucleotides downstream from the *Inr* TSS. When the LVGR promoter region of the archetype NCCR was analyzed, a similar composition with a dominant *Inr* and potential DPEs was found (Fig. 6B), but in contrast to the EVGR promoter with its conserved *TATA* box, two potential *TATA*-like elements were located upstream of the *Inr*/major TSS (Fig. 6B, plot below the sequence). Of note, this major TSS was in line with a previous mapping of the BKPyV late promoter by a primer extension assay (50). One of the *TATA*-like elements had two mismatches compared to the sequence of a perfect *TATA* box but showed the canonical distance of 30 nucleotides to the major TSS (*TATA*-like element 1; Fig. 6B), while the other had three mismatches and was located further upstream (*TATA*-like element 2). An additional potential CPE was identified as a transcription factor IIB (TFIIB) recognition element upstream (*BREu*), which is typically located directly upstream of a *TATA* box. Thereby, the promoter elements of EVGR and LVGR presented an imperfect symmetry of a classical *TATA* and a *TATA*-like promoter. Interestingly, in the case of the LVGR promoter, the *BREu* was adjacent to *TATA*-like element 2 and consisted of a GC-rich consensus sequence which partially overlapped *SPI-4* (Fig. 6B and D). This overlap of the LVGR *BREu* and high-affinity *SPI-4* raised intriguing questions about the functional implications with respect to the regulation of LVGR

expression through high-affinity Sp1 binding. It was therefore of interest to first examine deletion-bearing *rr*-NCCRs. As shown in Fig. 6C, the Dunlop *rr*-NCCR is characterized by a deletion of the  $Q_{35}$  and  $R_{63}$  blocks, which removes the *TATA*-like elements as well as *SPI-4*, and the dominant *Inr*, thereby disrupting the aforementioned imperfect symmetry of the late and the early sides of the archetype NCCR. The 5'-RACE analysis of the strain Dunlop NCCR revealed an overall dispersion of TSS but a slight overrepresentation of TSS at two potential *Inr* elements located in a canonical distance to the DPEs of 28 to 33 nucleotides (Fig. 6C, plot below the sequence). The results indicate that the loss of the LVGR CPEs could be partially compensated for by multiple initiator elements, which were found to be located throughout the triplicate P-block sequences and which acted in conjunction with the conserved DPEs of the S block. Together, the data indicate that the basal expression pattern of the archetype BKPyV NCCR involved an imperfect symmetry centering around a *TATA* box and *TATA*-like elements, which are modulated by juxtaposed Sp1-binding sites. Disruption of this basal symmetry by LVGR-proximal deletions was compensated for by the next-best fitting of analogous sequences.

**The *TATA* box is essential for both early and late expression.** To better understand the contribution of the respective core promoter elements for EVGR and LVGR expression, we designed a set of constructs in which we either removed defined sequence elements or changed them to obtain optimized consensus sequences but, again, without altering the overall length of the archetype NCCR. When we mutated the EVGR *TATA* box (Fig. 7A, *TATA* box-out, where "out" indicates that the CPEs were removed) or replaced it with a *TATA*-like element similar to the one at the LVGR (Fig. 7B, *TATA*-like-in early, where "in" indicates that the CPEs were inserted), not only was EVGR expression almost completely abolished but also LVGR expression was reduced to 23% of that of the archetype NCCR (Fig. 7K). These observations demonstrate the central importance of the *TATA* box not only for EVGR but also for the NCCR as a whole. In contrast, mutating the LVGR *TATA*-like elements individually or together (Fig. 7C to E, *TATA*-like-out late 1, *TATA*-like-out late 2, and *TATA*-like-out late 1 + 2) caused an increase in the level of EVGR expression to 10 to 15% of that of the archetype, while the level of LVGR expression was reduced to 20 to 25% of that of the archetype (Fig. 7K). Thus, effective LVGR expression from the late core promoter seemed to be equally dependent on both *TATA*-like elements, although the *TATA*-like element 1 sequence better matched a perfect *TATA* box and was situated within the canonical distances to the major TSS (Fig. 6B). When we mutated *SPI-4*, in addition to *TATA*-like element 1 (Fig. 7F, *TATA*-like-out late 1/*sp1-4*), LVGR expression went down by another 10%, suggesting a cooperative effect of the *TATA*-like element and the Sp1-binding site on the late promoter activity (Fig. 7K). Interestingly, changing the *TATA*-like elements individually or together to perfect *TATA* boxes did not increase the level of LVGR expression compared to that of the archetype NCCR (Fig. 7G to I, *TATA* box-in late 1, *TATA* box-in late 2, and *TATA* box-in late 1 + 2). Instead, the distance to the major *Inr* seemed to gain importance when a perfect *TATA* box sequence was inserted into the position of *TATA*-like element 1, as the level of LVGR expression then reached 35% of that of the archetype, while that of the corresponding construct with the *TATA* box-in late 2 reached only 23% of that of the archetype (Fig. 7K). Hence, the insertion of consensus *TATA* boxes in both positions diminished the LVGR promoter activity compared to that of the

**FIG 6** Experimental and computational core promoter analysis indicates the imperfect symmetry of the BKPyV archetype NCCR. The arbitrary sequences of the O, P, Q, R, and S blocks of the NCCR are shown on top. Selected nucleotide sequences enlarged with core promoter elements (CPE) are highlighted in the color of the respective sequence block, except for Sp1 sites, which are highlighted in yellow. Inr, initiator element; DPE, downstream promoter element (sequence in the dashed box highlighted in blue); *BREu*, TFIIIB recognition element upstream, overlapping (dashed box) with *SP1-4* highlighted in yellow; red nucleotides, mismatches compared to the CPE consensus sequence; vertical black lines, sequence block boundaries; horizontal black lines, distance (in nucleotides [nt]) from CPEs; dashed boxes, overlapping CPEs. The plot below the sequence shows 5'-RACE data, used to determine the transcription start site (TSS), with each point corresponding to the base pair position in the sequence presented above and the y axis showing the number of 5' reads for the respective position. (A) Analysis of early core promoter located at the O block-P block boundary. (B) Analysis of the archetype late core promoter in the Q, R, and S blocks. \*, position with the known polymorphism A/G, with G introducing an additional mismatch into the TATA-like element. (C) Analysis of Dunlop late core promoter with deletions removing the Q and R blocks. (D) Relevant CPEs with sequence logos, the consensus sequence in the IUPAC ambiguity code, and the typical position (Pos.) relative to the TSS (position +1) (45). R, A/G; W, A/T; S, C/G; Y, C/T; V, A/C/G; N, any nucleotide.

archetype, but the canonical positioning of the TATA box could partly compensate for this adverse effect. The single insertions showed an activation of EVGR expression of about 5-fold compared to that of the archetype (11% of that of the Dunlop strain),

and the double mutant TATA box-in late 1 + 2 showed EVGR expression in the range of 5% of that of Dunlop.

As mentioned above, the high-affinity *SP1-4* overlaps a potential *BREu*. Both share a GC-rich consensus sequence, and the

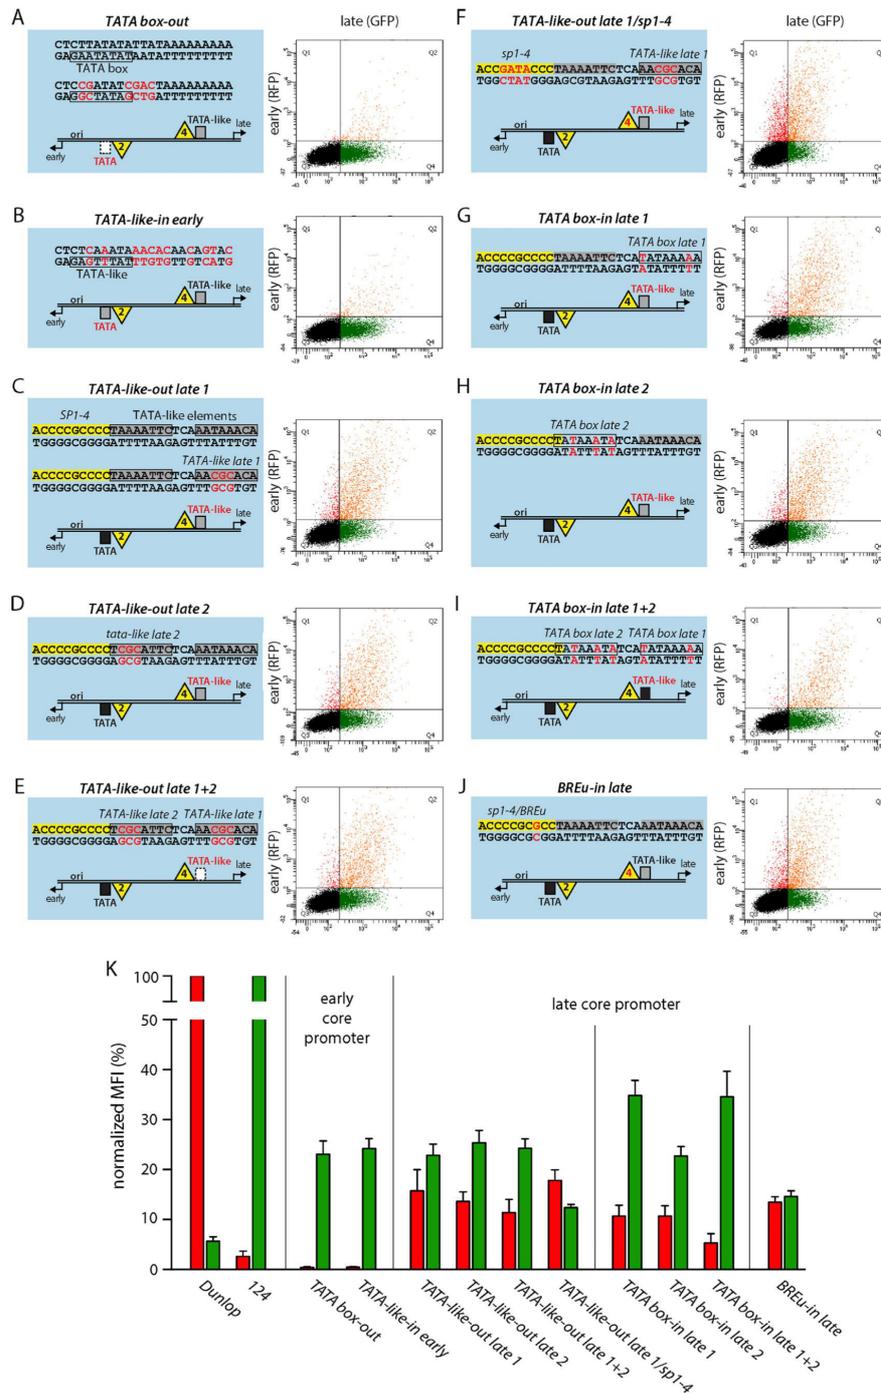

FIG 7 Mutating the EVGR TATA box or the LVGR TATA-like elements increases early expression. (A to J) (Left) The indicated mutant NCCRs inserted into the bidirectional reporter constructs were transfected into HEK293 cells. Red letters, mutations compared to the archetype sequence. CPEs were either removed (indicated "out") or inserted (indicated "in"). (Right) Representative FACS plots. (K) Quantification of the constructs listed in panels A to J using the normalized MFI from at least 3 independent replicates, as described in the legend to Fig. 1.

*SPI-4* site carries only one mismatch compared to the sequence of a perfect *BREu* site (Fig. 6D). Therefore, a point mutation was introduced to create a perfect consensus *BREu* site (Fig. 7), *BREu*-in late), which at the same time inactivated Sp1 binding, as shown for the previously analyzed *SPI-4* point mutations (Fig. 1). The results show that introduction of a perfect *BREu* consensus site did not increase the level of LVGR expression but, rather, reduced it to a level of about 15% of that of the archetype. At the same time, EVGR expression was increased only moderately to about 14% of that of Dunlop or 7-fold of that of the archetype. This finding indicates that the *SPI-4* site is more important than the potential *BREu* for driving LVGR expression.

**LTag can drive LVGR expression independently of archetypal late CPEs.** LTag is a major product of EVGR expression and an important regulator of the viral life cycle with respect to viral DNA replication and LVGR expression. We therefore compared the effects of critical NCCR mutants in HEK293, HEK293T, and HEK293TT cells, which produce no, small, or large amounts of SV40 LTag *in trans*, respectively (Fig. 8A). One essential function of LTag for the viral life cycle is to bind to the viral origin of replication (in the O block) and to facilitate, together with cellular factors, the replication of the viral genome (Fig. 8B). Interestingly, for almost all NCCR mutants tested, LTag was able to boost LVGR expression in a concentration-dependent manner. Despite variations in the absolute fluorescence intensities (Fig. 8C and D), most NCCR reporter constructs showed similar relative increases in the levels of LVGR expression in HEK293T and HEK293TT cells compared to the levels in their HEK293 cell counterparts (indicated by a dashed line, set to 1 for early and late fluorescence and each construct in HEK293 cells; Fig. 8E). The Dunlop strain, for example, which is characterized by a very low level of late expression in HEK293 cells, expressed 4 times more LVGR in HEK293T cells and 13 times more LVGR in HEK293TT cells than in HEK293 cells. At the same time, the level of EVGR expression of Dunlop stayed at the same level in the three cell lines. Since the LTag-mediated increase of LVGR expression was also observed with the Dunlop NCCR, which carries a large deletion of the archetypal late promoter elements (Fig. 6C), we concluded that LTag rendered LVGR expression independent of the expression of most archetypal late CPEs. This is in line with the finding that the *TATA*-like elements are dispensable, as observed with the construct *TATA*-like-out late 1, which showed an 8-fold increase in HEK293T cells and an 18-fold increase in HEK293TT cells compared with that in HEK293 cells. On the other hand, the highest absolute intensity (24,400 arbitrary units; Fig. 8D) and the highest relative increase (20-fold; Fig. 8E) in HEK293TT cells were recorded with the *TATA* box-in late 1 construct, which carried a perfect *TATA* box in a canonical distance to the major late *Inr* (Fig. 7G). We concluded that although the activating effect of LTag on LVGR expression could occur without the archetypal late promoter, there still seemed to be a benefit from the presence of a perfect *TATA* box and the high-affinity *SPI-4* site. The latter becomes visible when the levels of expression in the constructs NCCR *14r2r* and *14r4*, both of which carry the high-affinity *SPI-4* site in the early promoter but differ in the affinity of the late Sp1 site, are compared. While swapping of NCCR *14r2r* increased the level of LVGR expression by only 6-fold in HEK293TT cells, LVGR expression of NCCR *14r4* was boosted by 11-fold. However, LVGR expression of the archetype NCCR *124* was already high in HEK293 cells, which explains why the absolute and relative in-

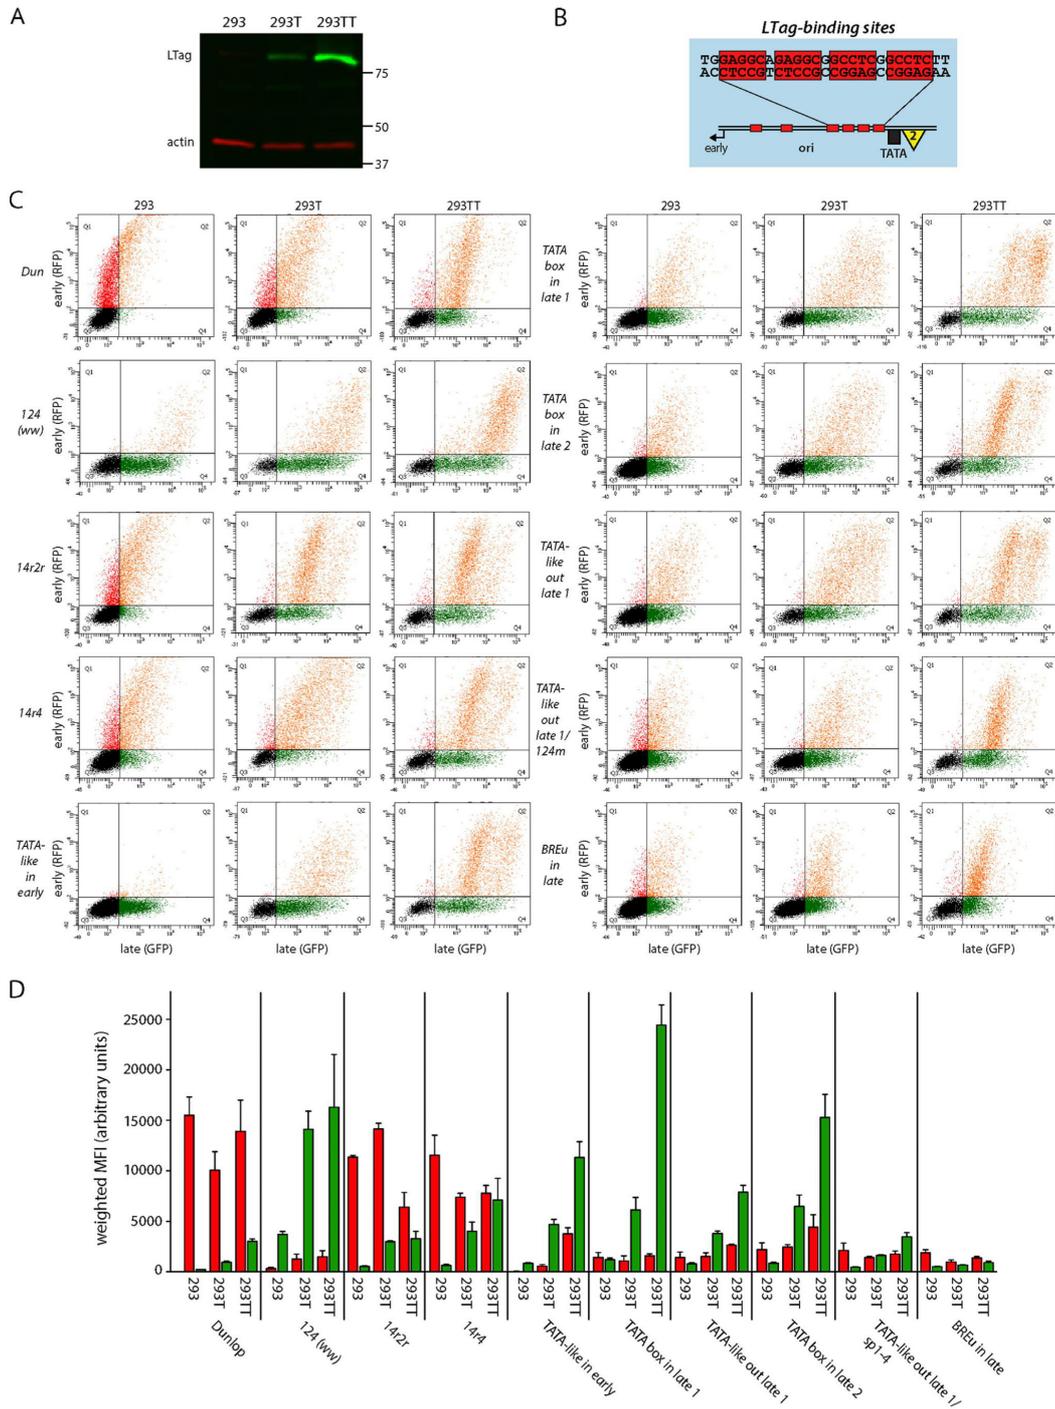

creases in HEK293T and HEK293TT cells were only moderate (4-fold). Intriguingly, LTag activation of LVGR expression also worked in the absence of the otherwise essential and conserved *TATA* box when it was compared in the EVGR mutants *TATA* box-out (not shown) and *TATA*-like-in early (Fig. 8C to E). The only exception to this LTag-mediated increase in LVGR expression was in the mutant NCCR *BREu*-in late, where a point mutation in the high-affinity *SPI-4* site created a perfect *BREu* site. Here, the increase in the level of LVGR expression was only 1.3-fold (HEK293T cells) and 1.8-fold (HEK293TT cells). Since both the *SPI-4* mutant (not shown) and the double mutant *TATA*-like-out late 1/*sp1-4* (Fig. 8E) were activated by LTag, we can only speculate at this point that the binding of TFIIB to the late promoter might pose an obstacle to LTag-mediated LVGR expression. Finally, we observed that EVGR expression remained similar for most constructs in this comparative transfection study, suggesting that the previously reported negative feedback of LTag on EVGR expression might be offset by increasing reporter construct replication. Notable exceptions to this observation were two constructs which had very low levels of EVGR expression in HEK293 cells, namely, the archetype NCCR *124* and the *TATA* box mutant *TATA*-like-in early. Here, few changes in early expression occurred, and these were probably attributable to plasmid copy number changes or an only subtle stimulation of the early promoter by LTag, which resulted in large relative increases in the expression levels.

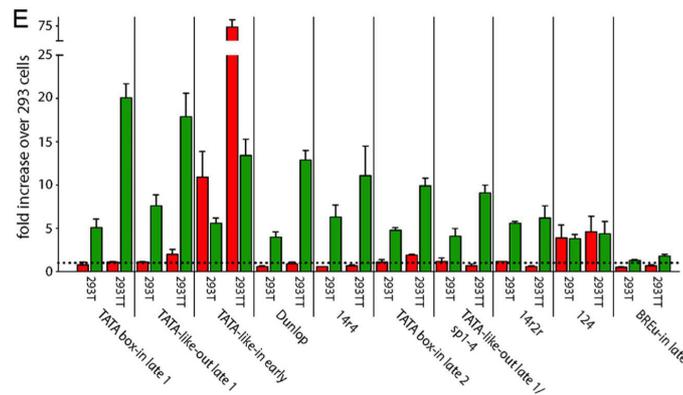

## DISCUSSION

The NCCR determines within only 400 bp essential functions of PyV biology, including viral persistence and the appropriate timing of virus gene expression, genome replication, and virion assembly. Whereas other similarly sized viruses, like members of the *Papillomaviridae* or proviral copies of the *Retroviridae*, use unidirectional promoter organization, PyVs have effectively evolved a complex bidirectional expression modality to sequentially role out a strand- and orientation-specific set of virus gene products from their NCCRs. Notably, these steps of the PyV life cycle are host specific and, within a given host, restricted to certain cells, arguing that cellular differentiation and activation states must be readily sensed and interpreted by PyV-specific NCCRs.

As the archetype NCCR of BkPyV is stably maintained in the general population, we were intrigued by the rapid real-time emergence of BkPyV variants with rearranged NCCRs in immunosuppressed kidney transplant patients and their functional link to increased EVGR expression, accelerated viral replication, higher blood viral loads, and more advanced pathology (31). Given the diverse array of affected TFBS in the *rr*-NCCRs, we recently introduced defined point mutations that excluded the potential effects of overall length and architecture on NCCR function and identified three phenotypic groups of TFBS (32): group 1 and group 2 mutations caused a strong and an intermediate level of activation of EVGR expression and viral replication, respectively, similar to that caused by natural BkPyV NCCR variants associated with disease, whereas group 3 mutations permitted only reduced or no NCCR function (32). Importantly, Sp1 emerged as a key regulatory factor, being able to mediate either extreme of the group 1 mutant (e.g., *SPI-4*) or the group 3 mutant (e.g., *SPI-2*) phenotype.

In the present study, we demonstrate that Sp1 can exert these differential effects as a result of the position, orientation, and affinity of two Sp1 TFBS located on the LVGR- and the EVGR-proximal sides of the archetype NCCR. Swapping of the low-aff-

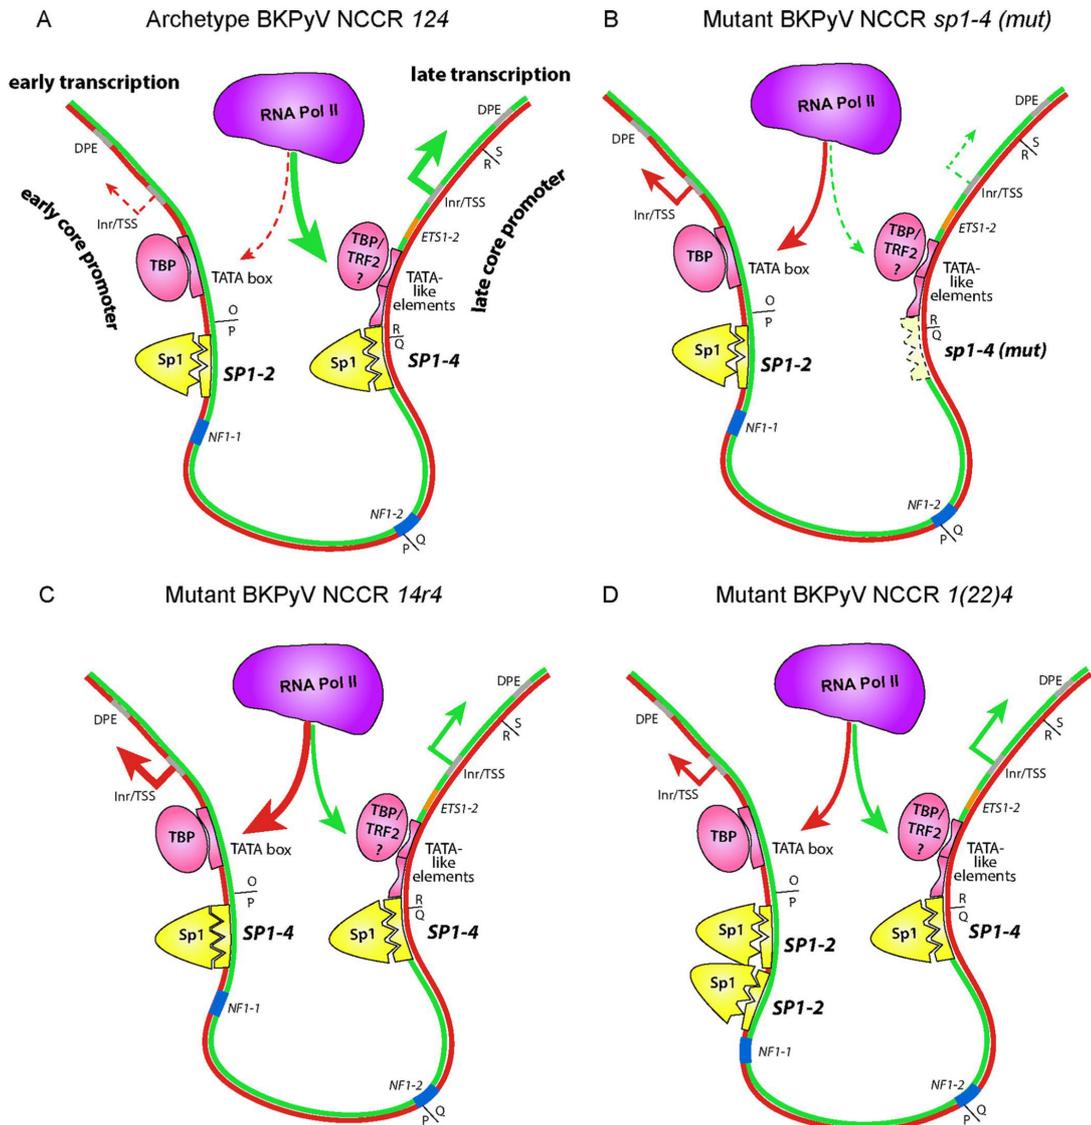

**FIG 8** LTag expression in *trans* increases the level of LVGR expression in a concentration-dependent manner and can drive late expression independently of core promoter elements. (A) Western blot showing the different LTag expression levels by HEK293, HEK293T, and HEK293TT cells and the level of actin expression as a loading control. Numbers on the right are molecular masses (in kilodaltons). (B) Schematic view of LTag-binding sites (sequences with a red background) in the O block of the BkPyV NCCR. (C) Representative flow cytometry of HEK293, HEK293T, and HEK293TT cells transfected with the indicated BkPyV NCCR bidirectional reporter constructs. (D) For quantification of EVGR and LVGR expression in the transfected cells, the normalized MFI (in percent) was calculated as described in Materials and Methods. The level of EVGR expression was normalized to that of strain Dunlop (red MFI = 100%), and the level of LVGR expression was normalized to that of NCCR 124 (*ww* archetype) (green MFI = 100%). Quantification was based on at least 3 independent replicates. (E) Relative change in the levels of EVGR and LVGR expression by the indicated reporter constructs in HEK293T and HEK293TT cells using HEK293 cells as a reference (for which the level of expression was set equal to 1 and is indicated by a horizontal dashed line).

finity *SPI-2* site and high-affinity *SPI-4* site (e.g., NCCR *14r2r*), introducing affinity-lowering mutations into the high-affinity *SPI-4* site [e.g., NCCR *12(4-5CG)*], flipping the Sp1 site orientation (e.g., NCCR *124r*), and creating various permutations and combinations thereof perturbed the EVGR-LVGR balance and in most cases led to a significant increase in the level of EVGR expression. In a key experiment, we made use of the construct NCCR *14r4*, which carries the same high-affinity *SPI-4* sequences in the respective EVGR- and LVGR-proximal positions, followed by introducing affinity-lowering mutations that caused a stepwise decline in the level of the activated EVGR phenotype. In another approach, the low-affinity *SPI-2* site was duplicated, showing that two low-affinity Sp1 sites were better than one or none, overall supporting the role of local Sp1-binding affinity. Importantly, the mutant NCCRs were functional in recombinant BkPyVs, yielding elevated viral replication compared to that of archetype BkPyV in RPTeCs, as predicted. Thus, the nonpalindromic nature of the Sp1-binding sequence and the deviations from its consensus sequence affected the directionality of expression and regulated the delicate EVGR-LVGR balance of the BkPyV archetype NCCR.

We also obtained evidence that the NCCR balance of the Sp1 sites acts in conjunction with core promoter elements (CPE), showing an imperfect rotation symmetry of a developmental promoter on the EVGR and a housekeeping promoter on the LVGR side of the BkPyV archetype NCCR. In general, most eukaryotic promoters can be assigned to (i) developmental or regulated promoters, which are characterized by a focused transcriptional start, that need to be activated by a stimulus and contain either a *TATA* box or a DPE and (ii) housekeeping or tissue-restricted promoters that are constitutively active and show multiple, dispersed transcriptional start sites, that are *BREu* enriched, typically without a *TATA* box, and that contain a CpG island (51, 52). Indeed, the EVGR side carries downstream of the Sp1 site a perfect *TATA* box

and one major *Inr*/TSS in a canonical distance of 31 bp, followed by a consensus downstream promoter element (DPE) at a distance of 28 bp (53, 54). Thus, our results indicate that the EVGR promoter of the BkPyV archetype NCCR fulfills the criteria of a regulated promoter with a perfect *TATA* box, a focused TSS, and a low level of basal activity. The LVGR promoter is less easily classified, since it bears the high-affinity *SPI-4* partially overlapping a potential *BREu*, followed by two *TATA*-like elements, a major *Inr* besides some dispersed TSS, and potential DPEs. We demonstrate here that the archetype BkPyV LVGR promoter shows a mixed focused-dispersed activity, which changes to a fully dispersed type of activity in the BkPyV Dunlop NCCR due to the deletion of the archetypal late promoter, extending the initial observation in hybrid NCCRs (50). The LVGR promoter is reminiscent of the previously described *TATA*-less housekeeping promoters described in the model of *Saccharomyces cerevisiae*, which essentially contain *TATA*-like elements (49). It is currently unclear whether *TATA*-like elements bind *TATA*-binding protein (TBP). One hypothesis is that they do but, compared to the results obtained with perfect *TATA* boxes, that binding leads to the assembly of altered preinitiation complexes (PIC), which—at least in yeast—have been shown to be Taf1/TFIID enriched (49). Alternatively, these kinds of sequences might be binding sites for paralogs of TBP, like TRF2, thereby leading to differential PIC formation and transcriptional activity. Accordingly, the imperfect symmetry of Sp1 sites, *TATA* elements, *Inr*, and DPEs in the BkPyV NCCR seems to allow the maintenance of the archetypal focus on the LVGR side while repressing EVGR expression. At the same time, this organization permits an effective bidirectional system that is highly poised to shift the transcriptional balance from LVGR to EVGR expression upon differential stimulation and mutation (32). A summary model of our findings is depicted in Fig. 9. It should be noted that a second layer of regulation that involves BkPyV microRNAs

**FIG 9** Sp1, TATA, and downstream promoter element (DPE) core promoter elements forming an imperfect symmetry underlying bidirectional EVGR and LVGR expression of the BKPvV NCCR. (A) BKPvV archetype NCCR *124* predominantly drives LVGR expression as a result of the high-affinity *SP1-4* (the three triangular indentations represent the zinc finger binding) and TATA-like elements, whereas EVGR expression is regulated by the low-affinity *SP1-2* site (two triangular indentations) and the TATA box. The Sp1 protein is depicted in yellow, with the three small triangles symbolizing zinc fingers. Pink ovals depict TBP (TATA box-binding protein) or TRF2 (TBP-related factor 2), with the latter potentially being recruited by TATA-like elements. A low level of early expression is due to less efficient recruitment of RNA polymerase II (Pol II) to the early promoter (red dashed arrows), and a high level of late transcription is due to recruitment of a major fraction of RNA polymerase II to the late promoter (fat green arrows). Inr, initiator element. For simplicity, other components, such as TFIIB and the TFIID complex or transcription factors like NF1, are not depicted (see reference 32). (B) Mutant BKPvV NCCR *124* carrying an *SP1-4* sequence with a point mutation (mut) that abrogated Sp1 affinity and thereby the recruitment of polymerase II to the late promoter, leading to a decrease in the level of LVGR expression (green dashed arrows). The low-affinity *SP1-2* now permits preferential recruitment of RNA polymerase II to the early promoter, causing increased levels of EVGR expression (red arrows). (C) Mutant BKPvV NCCR *14r4* in which the low-affinity *SP1-2* sequence was replaced with a high-affinity *SP1-4* sequence in the EVGR promoter. An increased fraction of RNA polymerase II is recruited to the early tandem of the TATA box and *SP1-4*, giving rise to high levels of EVGR expression (fat red arrows), while the unaltered late promoter is disfavored (green arrows). (D) Mutant BKPvV NCCR *1(22)4* carrying a duplication of the low-affinity *SP1-2* site in the early promoter increases RNA polymerase II recruitment and EVGR expression (red arrows), while the unaltered late promoter is disfavored (green arrows).

(miRNAs) also governs the effective control of EVGR expression. These miRNAs are transcribed in the late direction and target the EVGR transcripts, thus mediating repression of LTag expression (55). Thereby, persistent archetype BKPyV infection maintains a double-stitched mechanism to ensure tight control of LTag expression below the radar of the immune system (55, 56). In turn, activating rearrangements not only switch on EVGR expression but also overcome miRNA suppression, an alteration that requires the absence of a functional immune response (31).

The late DPEs located at the start of the S block are maintained in most patient isolates (31, 32), thus keeping the DPEs in place in *rr*-NCCR BKPyV variants lacking archetype late promoter sequences. Interestingly, these LVGR promoter deletions significantly increased EVGR expression at the expense of LVGR expression, but the associated increases in viral replication and progeny still depend on the corresponding expression of the LVGR structural gene products, e.g., Vp1, Vp2, and Vp3. We approached this issue by also providing two levels of SV40 LTag in *trans* in the HEK293 cell derivatives HEK293T and HEK293TT when transfecting selected NCCR mutants, thereby complementing the results of recombinant BKPyV infection in primary human RPT-ECs. The HEK293, HEK293T, and HEK293TT cell transfection experiments indicated that LTag expression in *trans* can overcome the adverse effects of deleting *SP1-4* or the TATA-like elements in the LVGR promoter. These results are in line with those of a previous study reporting that the SV40 LTag is able to rescue a crippled promoter function which was lost due to the lack of a TBP-associated factor (TAF), TAF(II)250 (57). TAFs and TBP have been shown to form the TFIID complex and target the core promoter region by binding to DPEs, *Inr*, and TATA elements (52, 58). Our data suggest that LTag is able to activate the LVGR promoter by executing a TAF-like function within the TFIID complex, helping to recognize the remaining CPEs, namely, the DPEs of the  $S_{63}$  block and the dispersed *Inr* in the  $P_{68}$  block of the NCCR. As mentioned earlier, few mutants also showed an increase in the level of EVGR expression, suggesting a small contribution of LTag to early promoter activity and/or an increase in episomal plasmid copy number via *ori*-binding functions. The NCCR *BREu*-in late mutant was a notable exception with respect to LVGR activation, as it showed little change in its level of expression in HEK293T and HEK293TT cells, suggesting a possible negative interference with LTag-mediated activation. This mutation abrogated Sp1 binding, while it introduced a perfect consensus *BREu*, thus indicating that the *SP1-4* site is more important than the potential *BREu* for driving LVGR expression.

This point mutational dissection of the bidirectional BKPyV NCCR may have implications for other HPyVs which show an architecture and an organization similar to those of BKPyV but which show a different TFBS composition and tissue specificity (59). In fact, NCCR rearrangements are best known from JC polyomavirus (JCPyV) variants from patient suffering from progressive multifocal leukoencephalopathy (46, 60–62). Following duplication of the early promoter and deletion of the late promoter sequences, the JCPyV *rr*-NCCRs demonstrate activation of EVGR at the expense of LVGR similar to those of BKPyV (46). These alterations also broaden the host cell range, which has particular relevance for neurotropism and pathology (34, 63, 64). Given the power of the bidirectional reporter construct to predict PyV NCCR expression and viral replication, our approach may

help to close the current knowledge gaps in viral host cell specificity and replication of the dozen novel human PyVs.

In conclusion, this study provides a novel view of the BKPyV NCCR by revealing an imperfect symmetry of the EVGR and LVGR promoter characteristics that are functionally balanced by the position, orientation, and affinity of Sp1 and core promoter elements. As there is currently no antiviral treatment available for BKPyV or the closely related JCPyV, this extended mechanistic understanding of the BKPyV NCCR might be utilized to design new therapeutic strategies targeting viral persistence and reactivation. Inhibition of EVGR promoter activation or the interaction of LTag with the LVGR promoter might open up the possibility of blocking viral infection while maintaining sufficient immunosuppression in transplant recipients.

We demonstrated that the affinity, position and strand orientation of Sp1-2 and Sp1-4 proximal to the EVGR and LVGR sites exerted different effects on BKPyV<sub>ww</sub> NCCR-driven EVGR and LVGR expression. Swapping the high-affinity Sp1-4 site and the low-affinity Sp1-2 site (e.g., NCCR *14r2r*), lowering the Sp1-4 affinity by introducing affinity-lowering mutations (e.g., NCCR *12(4-5CG)*), flipping the orientation of the Sp1 sites (e.g., NCCR *124r*) and various combinations of permutations upset the EVGR and LVGR balance and led to a significant EVGR expression in most cases. A step-wise lowering-affinity mutations caused a decline in EVGR expression in the NCCR *14r4* containing the high-affinity Sp1-4 site in respective EVGR and LVGR proximal positions. Duplicating the lower-affinity Sp1-2 site increased EVGR expression and elevated viral replication compared to BKPyV<sub>ww</sub>, suggesting that two lower-affinity sites were better than one or none. The non-palindromic nature of Sp1 sites and alteration from the consensus organization affected the BKPyV<sub>ww</sub> NCCR-driven EVGR-LVGR balance.

There was evidence, that the Sp1 regulatory balance of EVGR and LVGR acted in conjunction with CPEs showing an imperfect symmetry of Sp1, EVGR and LVGR core promoters with TATA and TATA-like elements. The EVGR of BKPyV<sub>ww</sub> NCCR fulfil the criteria of a regulatory promoter whereas LVGR promoter cannot be easily classified, but it is similar to a TATA-less housekeeping promoter described in *Saccharomyces cerevisiae*, which actually contains TATA-like elements.

Most rr-NCCR variants from patients lacking the late promoter sequences maintained the late DPEs. Deletion of the LVGR promoter increased EVGR expression at the expense of LVGR expression. However, progeny production relied on LVGR gene products. Transfection experiments of Sp1-4 and TATA-like elements deletion in the LVGR promoter in cell lines expressing different amounts of SV40 LTag showed, that LTag can overcome the effect of the deletions by increasing LVGR expression. The results corroborate previous studies showing that SV40 LTag was able to rescue a non-functional promoter lost due to lack of TBP-associated factor (TAF). Since TAFs and TBP have been shown to form the TFIID complex and bind the core promoter elements (DPEs, Inr, and TATA elements), LTag may activate LVGR promoter by exerting a TAF-like function with TFIID complex to recognize the remaining CPEs, the DPEs and the dispersed Inr.

The dissection of these different point mutations in BKPyV wv NCCR may also have implications for other HPyVs, especially those with similar NCCR architecture. Rearranged JCPyV NCCR variants from PML from patients showed EVGR promoter duplication and LVGR promoter deletion resulting in increased EVGR expression in the expense of LVGR expression similar to BKPyV.

This study revealed an imperfect symmetry of the BKPyV EVGR and LVGR promoter consisting of TATA and TATA-like elements, CPEs which function in conjunction with Sp1 binding sites to regulate the bi-directional balance of EVGR and LVGR expression. This knowledge can be used to design new therapeutic approaches against BKPyV infection, especially in transplant patients.

Manuscript under review.

### **5.5 Donor-derived urothelial cancer after kidney transplantation associated with a BK polyomavirus with increased oncogenic potential**

Potentially oncoproteins, Tags are encoded by all HPyVs. These viruses can cause cancer by interrupting cell proliferation control. The Tags interact with tumor suppressors p53 and pRB and drive the cell into S-phase, when components of the host DNA synthesis machinery are expressed to support viral DNA replication. A key concept in HPyV transformation has been that of permissiveness. Once HPyV enters a permissive cell and EVGR, DNA replication and LVGR happen, the outcome is productive infection. On the other hand, when HPyV infects a cell that cannot allow viral genome replication and LVGR expression, but supports EVGR expression, the outcome is cellular transformation (17).

BKPyV has been reported in 3 single cases of urothelial and renal tubular malignancies in the context of kidney transplantation. Additionally, in our study, BKPyV was found associated with urothelial cancer of the bladder (UC) in a kidney transplant recipient. The BKPyV genome was amplified by PCR from the extracted DNA of the tumor using outward primers from the Vp1 gene at the EcoR1 site and was sequenced. A full-length BKPyV genome (5116 bp) containing 17 bp deletion in

the p-block of the NCCR (P41-P57) and a shorter genomic fragment (3270 bp) lacking the NCCR, an N-terminal part of Vp2 and LTag was revealed. The viral genome was integrated into the cellular genome, and abundant BKPyV/SV40 LTag was detected in the tumor.

For functional analysis, the UC BKPyV NCCR was cloned into the bi-directional reporter vector pHRG, transfected in HEK293 cells and the EVGR and LVGR expression compared to that of BKPyV-DUN and BKPyV (ww)-NCCR reporter constructs. Recombinant viruses were made from two clones of the UC BKPyV NCCR variant and the replication was compared to that of BKPyVww, BKPyV-DUN and Sp1-4 BKPyV NCCR mutant described above in **section 5.3**.

**Abstract**

BK polyomavirus (BKPyV) increases the risk of developing urothelial carcinoma (UC) in immunosuppressed patients. Here, we performed a comprehensive genomic analysis of a BKPyV-associated, metachronous, multifocal and finally metastatic micropapillary UC in a 51 years-old kidney transplant (KTx) recipient. Dissecting cancer heterogeneity by sorting technologies prior to array CGH followed by short tandem repeat analysis revealed that the metastatic UC originated from the donor organ, a kidney from a 4-year-old boy at 10 years after transplantation. The top 50 cancer associated genes displayed no key driver mutations as assessed by next generation sequencing (NGS) of the cancer genome. Combining NGS of the viral genome and BKPyV-specific amplification provided evidence for full-length episomal and chromosomally integrated BKPyV (break point chr:1), both of which contained a unique and so far non-reported deletion in the non-coding control region (NCCR) of the BKPyV genome. This deletion resulted in impaired progression into the late viral life cycle and cytolysis. Consequently, urothelial cells are exposed to high levels of the early and transforming BKPyV proteins LTag and sTag from both, the chromosomally integrated and the episomal viral genome. To the best of our knowledge, this report links for the first time BKPyV-NCCR rearrangement with its transforming capacity in UC. A closer look at mutations BKPyV and the oncogenic implications is warranted in immunosuppressed patients.

## **Brief definitive report**

### **Introduction**

Several studies report an increased incidence of malignancies after solid organ transplantation. This was not explainable by the transmission of donor malignancies alone. Instead, recent findings indicate a role of infectious diseases in tumourigenesis [1, 2]. In particular, an association of BK polyomavirus (BKPyV) infection and the risk for urothelial cancer (UC) was suspected [3]. BKPyV genome contains three different functional areas, the early viral genome region (EVGR), the late viral genome region (LVGR) and the non-coding control region (NCCR). EVGR-proteins such as the large tumour-antigen (LTag) and the small tumour-antigen (sTag) have been identified as oncoproteins [4].

We report on a BKPyV-associated, multifocal, metastatic and micropapillary UC in a kidney transplant recipient. At the age of 42 years, he received a kidney from a 4-year-old male donor. Eight years post-transplantation (ptx), BKPyV/SV40 large T-antigen (LTag) positive UC of the bladder was diagnosed. A first recurrence appeared nine years ptx. Ten years ptx he was diagnosed with a BKPyV/SV40 LTag-positive, multifocal micropapillary and muscle-invasive UC with involvement of the graft kidney pelvis, the bladder wall and a single pelvic lymph node metastasis (Figure 1A, Figure S1A, Table S1) as evidenced after surgical removal of the organs.

Despite multiple recurrences and progression to metastatic UC disease, the patient has shown no evidence of UC during the 4 years of follow-up after surgery and termination of immunosuppressive therapy. Noteworthy, the patient had not received any systemic treatment other than termination of the immunosuppressive therapy.

## Material and Methods

In the course of routine diagnostics morphologic histopathological evaluation was performed. Immunohistochemistry identified the presence of polyomavirus using an antibody raised against the simian virus 40 (SV40) LTag (MRQ-4 mouse clone, Ventana Medical Systems, Inc., Tucson, AZ) on the Ventana BenchMark XT platform. Fresh-frozen tissue obtained from surgical specimen was used for further analyses. We applied DNA content based cell nuclei sorting prior to high-resolution genomic analysis by arrayCGH in order to discover the evolutionary history of this individual cancer [5].

To investigate the genealogy of the cancer tissues, we performed STR analysis. The investigated samples were the patient's innate kidney as a reference for recipient's DNA and healthy allograft-kidney tissue as a donor's DNA reference.

To further analyze the relatedness of the different tumour sites and to search for possible tumour-causing mutations we performed targeted NGS. The IonTorrent-platform by Life Technologies (Carlsbad, CA, USA) was used for sequencing. We performed targeted sequencing using the commercially available IonAmpliseq™ Cancer Hotspot Panel v2. 10 ng input of extracted genomic DNA was used for library preparation.

Extracted DNA from tumour and unaffected tissue were tested by a quantitative real-time PCR for BKPyV genome loads [6] and a human host cell gene (acetylase) was quantified for normalization per total number of diploid cells [7]. BKPyV-specific long-range PCR was performed using outward primers partially overlapping in EcoR1 site present in the VP1 gene [8] giving rise to a full-length BKPyV genome of 5116 bp and shorter derivative of 3500 bp for sequencing. The entire BKPyV genome was sequenced using different primer combinations either directly from the extracted tumour DNA following nested PCR or using the gel-purified long-range PCR products. The sequences were analyzed using codon code aligner (Codon Code Corporation, Centerville, MA, USA) and the FASTA files were depicted using ApE [9]. To detect potential chromosomal integration, shallow whole genome NGS was performed searching for BKPyV genome sequences using the Illumina NextSeq (Illumina, CA, USA) sequencing platform (10x average read depth). The libraries were prepared using the Illumina Nextera XT DNA Library Prep kit according to protocol. Reads were mapped against the hs37d5 reference genome as well as the BKPyV reference

sequence (NCBI acc. no. AB211371). Integration was called if read ends alignment to both reference sequences. Additionally, to sequence the BKPyV genome with higher coverage, targeted amplicon sequencing was performed on the Illumina MiniSeq with previously amplified amplicons of 5116bp and 3270bp and libraries prepared with Nextera XT DNA Library Prep kit. The data was analyzed with the CLC Genomics Workbench (Qiagen Bioinformatics, Denmark) and the Integrative Genomics Viewer (IGV, Broad Institute, USA). Primers spanning the integration breakpoints were designed based on detection of paired reads from whole genome sequencing aligning to the BKPyV reference sequence and chromosome 1 in the human genome (GRCh37/hg19). Using these primers, the integration of BKPyV into chromosome 1 was confirmed and the integrated parts of the genome sequenced by Sanger sequencing.

For a functional analysis, the NCCR of the BKPyV-UC genome was amplified, and inserted into the bidirectional reporter gene plasmid pHRG1, and sequenced as described previously [10, 11]. The respective NCCR pHRG1 reporter constructs were transfected into HEK293 cells and then quantified by flow-cytometry for EVGR expression (red fluorescence) and LVGR expression (green fluorescence) as described previously [11]. Recombinant full-length BKPyV genomes were generated by inserting the NCCRs derived from the Dunlop, WW archetype; archetype point mutant (*sp1-4*) and two BKPyV UC-derived NCCR clones CA1-2 and CA1-5 into the Dunlop genome as described previously [10, 11]. The recombinant BKPyV genomes were cut out from the plasmids and re-circularized prior to transfection of COS7 cells. Infectious supernatants from the transfected COS7 cells were harvested after 7 to 10 days for determination of the BKPyV load by real-time PCR [6]. Equivalent amounts were used for infection of human primary proximal renal tubular epithelial cells (hRPTECs) as described [10, 11]. The hRPTEC culture supernatants were harvested at 1, 3, 5, 7, and 9 days post-infection and BKPyV loads released into the culture supernatants were compared using real-time PCR [10, 11].

We obtained ethical approval from the Ethical Committee Nordwest- und Zentralschweiz in Basel, Switzerland (EKNZ 2014-313).

## Results and Discussion

ArrayCGH revealed that the UC (both, the metastasis and the bladder localization) most likely originated from the donor kidney pelvis (Figure 1B, Figure S1B). Adding short-tandem-repeat (STR) analyses confirmed that the UC originated from the graft kidney pelvis of an in summary 14 year-old donor organ. Surprisingly, we did not find any somatic key-driver point mutation by targeted NGS in 50 cancer genes (Table S2). Molecular characterization of the BKPyV strain in the 10y ptx cancer specimens revealed both integrated and episomal BKPyV genomes (Figure 2). The presence of the integrated BKPyV genome was detected only after performing whole genome NGS and identified the breakpoints in chr1:16055650\_PLEKHM2 and the capsid coding sequences of VP1 and Vp2/VP3, thereby deleting 1300 bp between VP1 and VP2/3 (Figure 2; supplement data). In addition, episomal BKPyV genomes consisting of a full-length and a smaller deletion episome was detected. Importantly, all three genomes carried the identical 17bp deletion in the non-coding control region (NCCR) of BKPyV (Figure 2;  $\Delta$ ATGACCTCAGGAAGGAA). This deletion was unique and affected NCCR sequences, which are rarely affected in other natural variants (Figure 3B), and contains a multitude of predicted transcription factor binding sites [10, 11]. Functional analyses in a bidirectional reporter assay revealed that this NCCR-variant is sufficient to significantly activate EVGR expression and contributes to LTag expression (Figure 3B). However, the NCCR-deletion impairs progression into the late viral life cycle and thereby offsets efficient lytic replication (Figure 3C). The intact full-length viral episome carrying the identical NCCR-deletion as the truncated integrated genome argue that this NCCR-signature deletion occurred first, and was followed by viral genomeintegration, both of which contribute to LTag expression.

Notably, this patient had a favorable outcome despite both, unfavorable pathological stage and histopathological features. Postoperative termination of immunosuppression alone without any neoadjuvant or adjuvant systemic chemotherapy was sufficient to control the disease. This points towards a strong transforming oncogenic force of aberrant LTag expression from a unique BKPyV-NCCR deletion, which cannot be cleared immunologically unless immunosuppression is discontinued. Indeed, recent work by Leboeuf et al. has demonstrated an important contribution of LTag-directed CD8 T-cells to BKPyV clearance in KTX patients [12].

It came as a surprise that the UC originated in the pelvis of an in summary 14 year-old donor kidney rather than in a 52 year-old recipient's urinary bladder that had a much longer history of potential exposure to carcinogenic agents, such as the actual ongoing cigarette smoking, and the accumulation of oncogenic events during lifetime. It remains challenging to dissect the relative contribution of immunosuppression and ongoing BKPyV replication during this process. It is well known that chronic immunosuppression by itself favors the development of malignancy [1]. However, one would expect pre-neoplastic conditioning by exposure to carcinogens or hereditary susceptibility before such cells can be unleashed to give rise to established cancer after release of immune control.

There is growing evidence that reactivation of polyomavirus infection under immunosuppression might play an important role in the development of aggressive UC after renal transplantation [13]. A driving role of BKPyV infection is also endorsed by the low mutational load in cancer related genes as compared to common urothelial carcinomas known to be among the malignant human tumors with the highest mutation rate [14]. This is in line with findings of low mutational loads in Merkel cell carcinoma, which is also known to be associated with BKPyV infection [15]. Intriguingly, all of the tumour manifestations of our patient across time (at 8y, 9y and 10y ptx) were SV40 LTag-positive, and eventually turned into a micropapillary variant at the final, most advanced stage. The micropapillary variant of UC has previously been linked to SV40 LTag-positive aggressive UC developed under immunosuppression [13]. The known association between SV40-LTag positivity with aggressive micropapillary morphology strongly suggests that BKPyV is not an innocent bystander infection, but rather acts as a driving oncogenic force in such a setting [16]. Although high-level BKPyV replication occurs in 30% of all patients after renal transplantation, the vast majority of UCs diagnosed in patients is SV40 LTag-negative, whereas the aggressive, SV40 LTag-positive UC is rare. The factors that render BKPyV oncogenic in individual patients remain largely unknown, but consistently are associated with constitutive EVGR expression encoding LTag and sTag [4]. Viral integration into the human DNA has been proposed as an important feature of oncogenic polyomaviruses disrupting constitutive EVGR- from lytic LVGR expression by interrupting LVGR gene-sequences. This can occur by breakpoints in the viral DNA either followed by host DNA [17] or further copies of viral DNA [18]. Such integration is supposed to support an imbalance between increased LTag expression and counteracting regulatory viral

elements, resulting in sustained perturbation of p53 and pRb, both binding to LTag. Our analyses provide evidence of both, NCCR-rearrangement and genomic integration, although the relative contribution of either in the last metastasizing state cannot be assessed. Our functional studies challenge the view that integration of polyomaviruses is a *condition sine qua non* to tumorigenesis. The deletion in the NCCR P-segment in a non-integrated BKV may lead to the same imbalance as reported before by the interruption of the LVGR [17, 18]. The 17bp deletion in the here reported virus constitutively activated LTag, and sTag EVGR expression, while impairing LVGR and the replicative capacity of isogenic derivatives. Therefore, the lytic virus replication with accumulation of viral particles and miRNAs and subsequent cell death appeared to be significantly impaired. Importantly, all stages of the UC in our patient were SV40 LTag positive suggesting that expression of this virus-encoded transforming function was not dispensable, but most likely contributed to malignant progression. Given the relapse-free time of 4 years after diagnosis of this metastasizing UC also points to the role of regaining anti-tumour immunity following stop of immunosuppression, in line with recent immunological studies [12].

Taken together, the rare occurrence of aggressive SV40 LTag-positive UC can be regarded as a “biological accident“ in the light of the high prevalence of high-level BKPyV replication in immunosuppressed patients e.g. after kidney transplantation [17]. However, given the high level of BKPyV replication and the huge number of viral generations in an immunosuppressed host, the odds for a rare clinical manifestation can be predicted to become a significant complication affecting the long-term perspective of otherwise successful kidney transplantation. Further studies are needed to explore the relative incidence and clinical importance of such alternative events.

## Figures

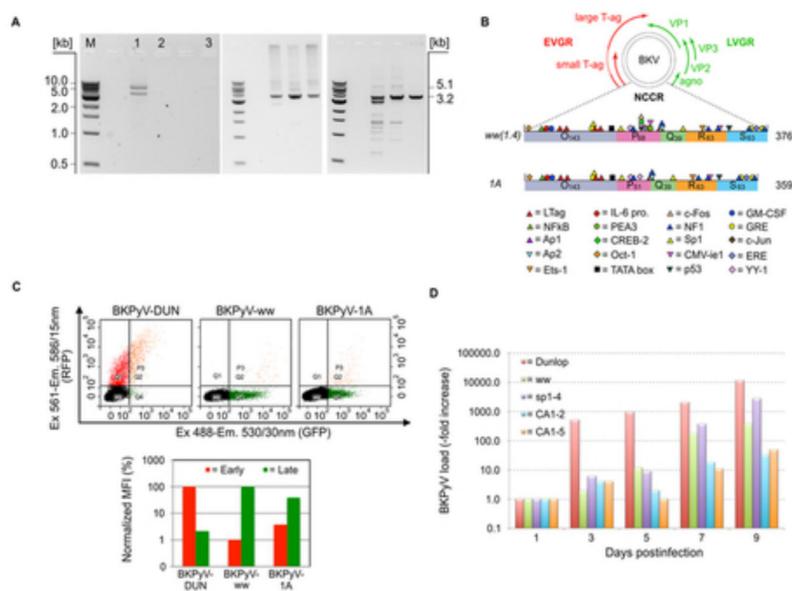

- 1 - Morphological and genomic characterization of cancer sites 10y ptx.
- 2 - BKPyV integration site
- 3 - Characterization of the BKPyV UC genome.

**Figure 1:** Morphological and genomic characterization of cancer sites 10y ptx. **A.** H&E-stainings and SV40-LTag IHC of micropapillary UC of the kidney transplant recipient at 40x magnification. The morphological picture indicates a close relationship of the different sites at 10y ptx and differ clearly from the previous tumour appearances (not shown). **B.** ArrayCGH profiles with copy number alterations of aneuploid cancer populations 10y ptx. Arrows indicate differences. X-axis: chromosome number; Y-axis: Normalized log<sub>2</sub> Cy3/Cy5 ratios (relative count of DNA-probe signals). The 10y ptx samples appear highly related. In contrast, there was no evidence of clonal relationship to the previous tumour appearances (not shown).

**Figure 2:** BKPyV integration site. Integrated and episomal BKPyV genome maps in urothelial cancer. The integrated genome and the breakpoints in chromosome 1 were located in the PLEKHM2 gene as identified by whole-genome NGS. The breakpoint sequences are shown above and colored in black (Chr 1) and green (BKPyV). In addition, a shorter and a larger episomal BKPyV genome of 5116 bp and 3270 bp was identified, all confirmed by specific PCR.

**Figure 3:** Characterization of the BKPyV UC genome. **A.** Amplification using outward primers overlapping in the EcoR1 site of the VP1 gene yields a full-length BKPyV DNA genome (5116 bp) bearing small deletion in the non-coding control region and a smaller sub-genomic fragment (3270 bp) lacking the amino terminal VP2, the NCCR, and the amino-terminal LTag region fragment. Lanes: M, DNA marker in kilobase pairs; 1, 50ng of UC tissue DNA; 2, negative template control; 3, weak BKPyV-positive urine as control Amplification chromosome 1 integrated BKPyV genome of 3786 bp by breakpoint-specific primers as confirmed by Sanger sequencing (supplement data S4). Lanes: M, DNA marker in kilobase pairs; 4-6, UC tissue DNA amplified by three different pairs of breakpoint-specific primers; 7-9, UC tissue DNA amplified by one pair of breakpoint-specific primers with a gradient PCR (61°C, 63°C and 65°C). **B.** Schematic comparison of the transcription factor binding sites in the BKPyV archetype NCCR (ww1.4) of 376 bp, and the BKPyV 1A NCCR (359 bp) detected in the urothelial cancer shows the deletion of 17 bp in the P-block P41-P57;EVGR, early viral gene region; LVGR, late viral gene region.**C.** NCCR-driven expression of EVGR (red fluorescence; dsRed) and LVGR (green; EGFP) in the bi-directional reporter vector pHRG1 following transfection into HEK293 cells (top panels: flow cytometry; bottom panels: normalized mean fluorescence intensity). **D.** Comparison of viral replication in Vero cells after transfection of the indicated BKPyV NCCR variants: Dunlop strain,

archetype WW(1.4); WW(sp1-4) mutant; and two independent recombinant clones bearing the cancer NCCR CA1-2 and CA1-5.

## **SUPPLEMENTARY INFORMATION**

1 – Supplementary PATIENT AND METHODS

2 – Supplementary RESULTS

3 – Supplementary FIGURES

4 – Supplementary TABLES

### **1-Supplementary PATIENT AND METHODS**

#### *Patient*

The recipient suffered from end stage renal disease due to Alport-syndrome. The donor's HLA-status was: blood type: A+; HLA-A: 1, 2; HLA-B: 8, 27; HLA-DR: 13, 7. In comparison, the recipient's status was: blood type A+; HLA-A: 24, 26; HLA-B:44, 50; HLA-DR: 13, 7. The immunosuppressive therapy consisted of tacrolimus, azathioprine, and prednisone for the first 6 months post-transplant (ptx) followed by tacrolimus and azathioprine. 3 months ptx a tissue biopsy was SV40-IHC negative. No further SV40-IHC staining on non-cancerous tissue was performed. 6 months ptx decoy cells were found in the patient's urine (11 /10 High Power Field 400x). Previous urine specimens did not show any decoy cells. In summary, there was no evidence for BKPyV-associated nephropathy (BKPyVAN). Thirteen years after transplantation, the patient is alive but requires continued renal replacement therapy by dialysis. PET/CT scans show no evidence of the urothelial cancer.

#### *Cell nuclei extraction and DNA content-based cell sorting*

For the purpose of dissecting the intratumour heterogeneity within one tissue-sample we performed DNA based cell sorting. Formalin fixed and paraffin embedded (FFPE) tumour specimens were analyzed morphologically with the Axioskop 2 plus microscope (Zeiss, Oberkochen, Germany). Biopsy samples were fixed in 10% buffered formalin and embedded in paraffin according to standard operating procedures. Cell nuclei extraction was done as previously described [19]. The extracted nuclei were separated by DNA content based on sorting using the Influx (Becton-Dickinson, San Jose, CA) cytometer with ultraviolet excitation. DNA content

and cell cycle were analyzed using the software program MultiCycle (Phoenix Flow Systems, San Diego, CA). Sorted nuclei were digested overnight in 180 µl of Incubation Buffer (Promega Corporation, Madison, WI) and 20 µl of Proteinase K (Promega Corporation, Madison, WI) at 56°C, 650 rpm for genomic DNA extraction.

#### *DNA extraction*

Total genomic DNA from sorted populations was extracted with MaxWell 16 FFPE Plus LEV DNA Purification Kit (Promega Corporation, Madison, WI) according to the kit protocol. For NGS purposes, DNA was also directly extracted from the matched FFPE tissues without sorting. Two to three 25 µm sections were placed into 2 ml microtubes. Samples were washed three times with 1 ml Xylene for 5 min to remove the remaining paraffin, following rehydration two times in 1 ml 100 % EtOH, which was then evaporated for 2 min in 26°C. 180 µl of Incubation Buffer (Promega Corporation, Madison, WI) and 20 µl of Proteinase K (Promega Corporation, Madison, WI) were added. Samples were digested overnight at 56°C, 650rpm and DNA was extracted with MaxWell 16 FFPE Plus LEV DNA Purification Kit (Promega Corporation, Madison, WI) according to the kit protocol. Because of impurities of DNA of the 2011 and 2012 samples were purified with Genomic DNA Clean and Concentrator Kit (Zymo Research, Irvine, CA) before using these samples for next-generation-sequencing (NGS).

#### *Array comparative genomic hybridization (aCGH)*

In order to investigate copy-number changes within the different tumour populations we performed aCGH. Genomic alterations between samples were evaluated with Agilent SurePrint G3 HMN CGH 4x180 K Oligo Microarray Kit (Agilent Technologies, Santa Clara, CA) according to the manufacturer's protocol. 40-100 ng DNA of each sorted population was subjected to the arrays and normal Female Human Genomic DNA (Promega Corporation, Madison, WI) was used as a reference DNA during aCGH. Reference DNA was digested with DNase I. References and samples were labelled with Cy-3 dUTP and Cy-5 dUTP respectively, using a BioPrime Array Kit (Invitrogen, Carlsbad, CA). Filtering, hybridization and washing were carried out according to manufacturer's protocol (Agilent Technologies, Santa Clara, CA, USA).

#### *Short tandem repeat analysis (STR)*

DNA was purified using the Genial<sup>®</sup> DNA Kit according to the provider's protocol for isolation of total DNA. The DNA was eluted in 30 µl of low TE-buffer. All profiles were genotyped with the PowerPlex<sup>®</sup> ESI 17 Kit (Promega Corporation, Madison, WI). The kit is based on a five dye technology (blue: 6-FAM<sup>™</sup>, green: VIC<sup>®</sup>, yellow: NED<sup>™</sup>, red: PET<sup>®</sup>, orange: LIZ<sup>®</sup>) and contains 16 autosomal STR loci and AMEL (blue: D10S1248, vWA, D16S539, D2S1338; *green*: AMEL, D8SS1179, D21S11, D18S51; yellow: D22S1045; D19S433, TH01; FGA; red: D2S441, D3S1358, D1S1656, D12S391, SE33; orange: internal standard). Each run was performed on an Applied Biosystems Genetic Analyzer 3500 (Life Technologies, Carlsbad, CA, USA) with injection voltage 3 kV and injection time 10 seconds. Results were then analyzed with the GeneMapper IDX Software (Version 1.4). The peak threshold was 50 rfu (relative fluorescence units). In order to define the recipient's profile available FFPE tissue from the recipient's innate kidney was used. No non-transplanted donor tissue was available. To define the donor's STR-profile we took healthy FFPE-tissue in adequate distance from the tumour from the allograft. The extracted DNA from the recipient's innate kidney was diluted 1:100 for further analyses.

#### *Next generation sequencing (NGS)*

The panel used for targeted sequencing includes 207 amplicons covering mutations from 50 oncogenes and tumour suppressor genes. Chiploading was assisted by the IonChef-System (Life Technologies, Carlsbad, CA, USA). For Sequencing we used the LifeTech Personal Genome Machine (PGM) (Life Technologies, Carlsbad, CA, USA). Sequencing data was analyzed using the IonReporter<sup>™</sup> software pipeline (Life Technologies, Carlsbad, CA, USA). Manual review was performed on called mutations in order to reduce the number of false positive calls.

## **2-Supplementary RESULTS**

#### *Histopathology*

The morphological picture of the early tumours from 8 (pTa, high-grade) and 9 years ptx (pT1, high-grade) differs from the one of the three sites obtained 10 years ptx (pT3, G3). In the 8y- and 9y-ptx tissue samples, we saw an ordinary high-grade urothelial carcinoma. The 8y-ptx tumour was papillary while the 9y-ptx tissues also had a solid component. However, the 10y-ptx samples showed a micropapillar morphology,

clearly differing from the previous tumour appearance. The histopathological findings of all tumour manifestations are summarized in Table S1.

#### *DNA content based cell sorting of tumour-specimen and aCGH*

Fluorescent activated flow sorting of cell nuclei from tumour tissue based on DNA content indicated that all analyzed tumour samples were composed of a diploid and an aneuploid tumour cell population. We further investigated the aneuploid populations by arrayCGH. The aneuploid populations from 8y- and 9y-ptx displayed distinct genomic differences with each population harboring several private amplifications and deletions (Figure S2). Consequently, there was no evidence of clonal relationship among these tumours. Furthermore, both aneuploid populations from 8y- and 9y-ptx clearly differed from the three aneuploid 10y cancer samples suggesting that the 8y, 9y and 10y-ptx tumours each represent genomically independent cancer manifestations. Conversely, the aneuploid populations sorted from the pT3 renal pelvis, the pT3 bladder and the metastatic lymph node manifestations at 10y-ptx shared a common profile. The only exceptions were a private amplification at 6p12.3 and a private deletion at Xp22.33 - Xp22.11 in the bladder manifestation of the 10y-ptx tumour (see Figure S3 + Figure 1B). Regarding the copy number variations (CNV) of relevant tumour suppressor genes and oncogenes in the 10y ptx samples, we found low-level gains in *CTNNA1*, *ERBB2*, *GNAS* and *SRC*. ArrayCGH did not show any deletions of tumour suppressor genes. All microarray files have been deposited at the National Center for Biotechnology Information Gene Expression Omnibus (accession number GSE90778).

#### *Short tandem repeat analysis (STR)*

DNA-amplification of tumour samples from year 8 and 9 was not successful presumably due to poor DNA quality. However, bulk-tissue cuts of all 10y cancer samples as well as several healthy tissue samples from the donor and the recipient were suitable for STR analysis. We could define a distinct recipient's healthy profile in all 16 STR-systems. Due to contamination with recipient derived blood cells or ingrown stromal cells we expected the donor's healthy specimen to show a mixed profile. As such, main-profile (MP) and a side-profile (SP) were discriminated in the donor's healthy specimen. All detected alleles of the SP were identical with the recipient's profile. All 10y-ptx cancer specimens showed a mixed profile consisting of a donor

derived MP and a recipient derived SP. The detailed STR-results are depicted in the Table S3.

In summary, the STR analysis demonstrated that the 10y-ptx cancer manifestations identified in the allograft kidney pelvis (pT3), in the patient's own bladder (pT3a / CIS) and in a single pelvic lymph node metastasis, were all of donor-origin.

#### *Next generation sequencing*

Polymerase chain reaction (PCR) based DNA-amplification of tumour samples from 8y- and 9y-ptx was not successful (see above). However, NGS revealed 18 genomic nucleotide variants in all three 10y-ptx cancer samples. According to the University of California, Santa Cruz (UCSC) common single nucleotide polymorphism (SNP) database, 15 of them were reported SNPs. In none of the investigated 50 cancer genes somatic mutations were identified. The remaining three nucleotide variants are not yet classified SNPs or known somatic mutations by publicly available databases. Of these, one did not pass a threshold of 10% allele ratio and therefore has a high odd for being an amplification-artefact. The two other nucleotide variants were: *KDR* / InDel chr4:55962545 and *Akt1* / c.138C>A. Further details are shown in Table S2.

#### *Characterization of the BKPyV UC*

The BKPyV viral load in the 10y-ptx UC tissue samples was determined by real-time PCR as 1 BKPyV copy per diploid human cell using the human acetylase gene as normalization reference [20, 21] . No BKPyV DNA could be detected in healthy tissue from the same time point. To characterize the BKPyV UC genome, two primers targeting the conserved EcoR1 site in the BKPyV VP1 capsid gene were used in an outward orientation. As shown in Figure 2A, two fragments corresponding to a full-length BKPyV genome of 5,116 bp and a shorter fragment of 3,270 bp were generated, whereas no products were obtained from unaffected tissue DNA. Sequencing of the larger fragment revealed a complete BKPyV genome bearing a total of 49 single nucleotide differences from the BKPyV archetype sequence in LTag, sTag, VP1 and VP2 (data not shown), with the exception of a 17 bp deletion in the P-block of the NCCR (Figure 2B). The shorter fragment represented a truncated BKPyV genome due to a 1.9 kb deletion from the small T-antigen coding region at bp position 4668 to the VP2 coding region at position 1398 bp, which removed the N-terminal coding region of LTag and sTag, and the NCCR, and thereby could not account for the LTag-positive

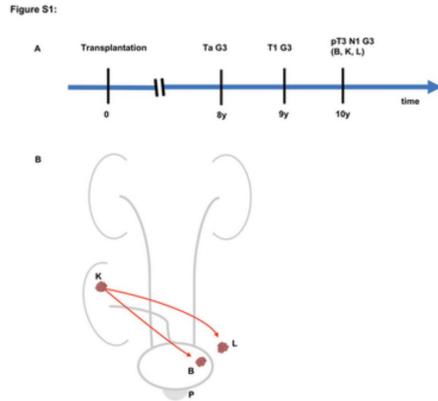

staining. Also removed were the entire agnoprotein and N-terminal parts of the VP2, while the remaining part shared all 36 single nucleotide differences present the complete BKPyV UC genome. These results were confirmed by direct nested PCR and sequencing from the UC tissue. Given the unique BKPyV UC del-NCCR and the well documented role of NCCR rearrangements for constitutive up-regulation of the BKPyV EVGR expression at the expense of LVGR expression [22], a functional analysis was performed by inserting the BKPyV UC-NCCR into the previously described bi-directional reporter construct carrying the red fluorescent protein (dsRed) and the green fluorescent protein (EGFP) as markers for EVGR and LVGR expression, respectively (Figure 2C). Following transfection of human embryonic kidney (HEK) 293 cells and single-cell analysis by flow cytometry, the UC 1A-NCCR conferred a moderate activation of EVGR expression (red) of 2 – 3 fold as compared to the archetype BKPyV ww-NCCR carrying the full-length sequence. To investigate effects of the UC-NCCR deletion on viral replication, recombinant BKPyV genomes were generated that only differed in the respective NCCR and then compared for replicative capacity following infection of hRPTEC cells (Figure 2D). The results demonstrate that the replicative capacity of the BKPyV UC-NCCR strain was significantly impaired compared to the archetype ww-NCCR. In contrast, the laboratory adapted Dunlop-NCCR or a recently identified point mutant *sp1-4*-NCCR showed a much higher replication rate (Figure 2D). Taken together, the molecular characteristics of the BKPyV-UC strain suggest that this variant significantly activates EVGR expression and contributes to LTag expression, but that this unique 17bp deletion impairs progression into the late viral life cycle and thereby offsets efficient lytic replication.

### 3 - Supplementary FIGURES

The first column shows the name of DNA-probe (marker). Numbers and letters in columns two to six show alleles (two per chromosome) where DNA-probes annealed. underlined numbers: recipient related alleles; **bold numbers**: donor related alleles; ( ): side profile's alleles; n.r.: no signal reported.

The molecular characterization of the BKPyV full-length genome revealed an NCCR with 17 bp deletion located in a region rarely affected in other naturally occurring BKPyV variants. Like most rearranged BKPyV NCCR variants from patients, this 17 bp deletion increases EVGR expression in expense of LVGR expression, and may contribute to the LTag expression detected in the UC. However, this deletion prevented progression of the viral replication cycle into the late phase, therefore obstructing progeny production. Integration of the viral genome into the host genome or LTag interaction with tumor suppressors can result to tumorigenesis. There was evidence of viral genome integration into the host's chromosomes.

Altogether, this study reports an oncogenic role of a rare BKPyV variant with a unique 17 bp deletion in the NCCR. This deletion activated EVGR expression in expense of LVGR expression however, a reduced viral replication probably due to integration in the cancer genome. Larger number of cases would be needed to confirm these findings.

## 6 DISCUSSION

We showed that the HPyV-NCCRs differ in sequences, length, number of LTag-binding sites and TFBS. These differences in the NCCRs and cellular transcription factors make-up are essential for the differences of the HPyV-NCCRs activity in the cell lines. Interestingly, some HPyVs demonstrated high EVGR or LVGR expression in cell lines derived from tissues where they were hypothesized to have tropism for, suggesting tissue tropism in the respective body compartment where those cells were derived from. LTag is vital for HPyV genome replication and LVGR expression (59, 262, 345). Thus, the effect of exogenous Tags expression on HPyVs EVGR and LVGR expression was characterized. SV40 Tags were able to activate both EVGR and LVGR expression from the NCCR of all HPyVs. Additionally, MCPyV cognate Tags activated EVGR expression from the MCPyV NCCRs, expression indicating the bidirectional reporter recapitulates an essential NCCR response described for the viral life replication cycle (25, 48, 340, 346). Replication and viral production of MCPyV and BKPyV in HEK293-4T cells expressing both MCPyV Tags and SV40 Tags have been reported (347). Furthermore, BKPyV and JCPyV demonstrated productive replication in HEK293TT cells, expressing SV40 LTag (306). Taken together, these and our results support the hypothesis that cell lines expressing cognate Tags of respective HPyVs may support propagation of respective HPyVs. We also noticed that HPyVs' number of LTag binding sites correlated with EVGR expression in HEK293T cells expressing SV40 Tags, indicating a role for LTag-binding sites in HPyV EVGR and LVGR expression. The role of BKPyV LTag binding sites in EVGR and LVGR expression, which can be extrapolated to other HPyVs, was investigated for BKPyV as a model HPyV in **Section 5.3**. We showed that rr-NCCR variants of HPyV7 (HPyV7-PITT1 and -2) and HPyV9 (HPyV9-UF1) from patients displayed higher EVGR expression compared to their respective archetype, indicating that rearrangements in the NCCR of novel HPyVs may also result in gain of function for EVGR expression and probably higher viral replication rate as demonstrated for clinical variants of BKPyV and JCPyV (26, 34). This result emphasizes the fact that the NCCR is the pathogenicity determinant of HPyVs. Interestingly, the higher EVGR expression pattern of the novel HPyV (rr)-NCCRs of HPyV7 and HPyV9 differs in the cell lines, indicating that the host cell's TFs make-up

are also implicated in the NCCR-driven expression. More so, a BKPyV variant from a urothelial cancer harboring a unique 17 bp deletion in the NCCR led to a gain of function for EVGR expression (section 5.4). This BKPyV variant expresses abundant LTag in the urothelial cancer, but surprisingly showed an impaired viral replication *in vitro*. This indicates that not all NCCR variants with elevated EVGR reporter expression correspond to an increase in viral replication, especially in the context of tumorigenesis. Other components of the viral-host cells interaction such as viral-receptor entry or viral release may be involved. This impaired *in vitro* viral replication may also be due to viral integration into the host genome as reported not only in the urothelial cancer case study in **section 5.5**, but also for MCPyV integrated into the genome of Merkel cell carcinoma (348). The data are important for identifying host and viral factors vital for the replication of HPyVs in cell culture and comprehending secondary host cell tropism for HPyV beyond HPyV entry. This will go a long way in understanding the basic biology of these important human viruses. However, further studies are needed to determine the actual replication of some of the HPyV-NCCRs with high activity in cell lines.

In the following part of the thesis we focused on the regulation of HPyVs using BKPyV as a model HPyV. A role of LTag binding motifs in EVGR and LVGR fold expression in cell lines constitutively expressing LTag was suspected, although a role of each particular LTag binding site is unknown. LTag-binding motif of SV40 have been greatly studied (59). The key feature of LTag in the NCCR of SV40 is its ability to bind the motifs GRGGC located at the ori, to regulate viral transcription and promote viral genome replication (59, 262, 345). All HPyVs including SV40 share a common genome architecture and all contain LTag binding sites in their NCCRs. However, there are some important features in which HPyVs differ. For instance, their secondary host cell tropism (NCCR activity in host cells), NCCR length, viral control elements for example, ori, EVGR and LVGR promoters, and location and number of LTag-binding sites. All HPyVs encode at least one LTag-binding motif located mostly at the ori. Since the roles of the SV40 LTag motifs are greatly known and the motifs between SV40, BKPyV and JCPyV at the ori are the same, we hypothesized that the role of the LTag binding motif in BKPyV is similar to those of SV40, which can be extrapolated to other HPyVs. The EVGR and LVGR expression of BKPyV ww-NCCR reporter with those of BKPyV ww-NCCR defective in one or

more LTag binding motifs was compared in HEK293 cells expressing no, small or large amounts of SV40 LTag. Eight different combinations of permutations were made in the BKPyV ww-NCCR LTag-binding motif (termed A, B, C, D, AC, ABC, ACD and ABCD). Our results revealed that EVGR expression of the ww-NCCR, increases in HEK293T cells and then decreases in HEK293TT cells. Mutating the LTag binding *site A* or combination of LTag binding *site A* with other LTag binding sites interestingly, abrogated this EVGR expression decrease in HEK293TT cells. This indicates that LTag may interact with LTag binding *site A* to exhibit this decrease. Mutation of other LTag binding sites together with LTag-binding *site A* did not affect this EVGR decrease in HEK293TT cells. With respect to the LVGR expression, all LTag-binding site mutants showed a proportional increase in LVGR expression in the presence of increasing amounts of LTag expression. Nonetheless, this proportionate LVGR expression is abrogated in mutants containing both *A* and *D* LTag-binding sites mutation. Intriguing, mutants containing either *A* or *D* LTag binding sites still exhibited the proportional LVGR expression. This result suggests that LTag-binding *sites A* and *D* may be involved in the LVGR-expression increase in the present of abundant LTag expression (HEK293TT cells) or the increase could be due to plasmid copy number effects (**Fig. 4C**). However, our preliminary reporter plasmid quantification by qPCR did not exactly correlate with the reporter constructs expression, thus indicating the expressing differences may not be due to plasmid copy number effects. The results obtained from investigating the LTag-binding sites of BKPyV can be extrapolated to other HPyV, such as JCPyV with similar LTag-binding sites organization. In this study, we analyzed the effect of SV40 LTag on the BKPyV ww-NCCR mutants defective of LTag-binding motif knowing that one cannot exclude that BKPyV cognate LTag might give different results. Nonetheless, the SV40 and BKPyV LTag have great similarity (47) and the fact that BKPyV can replicate in HEK293TT cells constitutively expressing SV40 LTag argued against this possibility (306). EVGR and LVGR expression were analyzed using the bi-directional reporter vector omitting viral replication. Thus, further experiments are required to quantify the viral replication potential of the various NCCR mutants defective of LTag-binding motif by cloning them in a BKPyV-dunlop backbone and perform viral replication studies in cell culture as previously described (34).

In conclusion, this thesis gave novel insights into the host and viral factors that may be vital for identifying suitable cell culture systems for HPyVs replication and prediction of HPyVs secondary host cell tropism. This will greatly enhance our understanding of the basic biology of HPyVs and development models for anti-viral testing. Finally, the effect of LTag-binding sites mutageneses suggests LTag-binding sites A and D may play a crucial role in the regulation of BKPyV's EVGR and LVGR expression.

## 7 SUPPLEMENTARY MATERIAL AND METHODS

### Dual reporter design and Primers

We designed a new-smaller bi-directional reporter pRG13 (**Fig. 1A**) based on the phRG reporter described in Gosert et al (**Fig. 13**), (25). The reporter lacks the SV40 early promoter, beta globulin polyadenylation signal and Hygromycin gene sequences found in the phRG (**Fig. 13**). Furthermore, a derivative reporter vector (pRG13D12) which lacks only 12-nucleotide sequence of BKPyV *ww* agno gene (nucleotides number 4-15) compared to pRG13 was designed. The pRG13 and pRG13D12 reporters were designed as follows: a pBI-CMV2 plasmid (**Fig. 14**) containing a bidirectional CMV promoter, a green fluorescent protein reporter gene from the *Aequorea coerulea* jellyfish (AcGFP1), Ampicillin resistance gene, SV40 poly-adenylation signals and Colicin E1 origin of replication was ordered (clontech, Germany). The plasmid was digested with NotI and Apal restriction enzymes (New England Biolabs, England). The digestion product was visualized on a 1% agarose gel (Thermo Fischer Scientific, Switzerland). A 2385 bps fragment comprising of the ampicillin resistance gene, SV40 poly-adenylation signals and Colicin E1 was purified from the gel with the nucleospin extract II columns (Macherey-Nagel, Switzerland). Next, from the phGR reporter vector (25) a 1803 bps fragment comprising of the enhanced green fluorescence protein (EGFP), BKPyV Dunlop NCCR containing the 12-nucleotide sequence and the *Discosoma striata* red fluorescent protein 2 (DsRed2) was PCR amplified with primers (**Table 3**). The PCR product was digested with Apal and NotI and then purified with the nucleospin extract II columns. DNA concentrations were estimated using a NanoDrop 1000 spectrophotometer (Thermo Fischer Scientific, Switzerland). The 1803 bps fragment was ligated using T4 DNA ligase (New England Biolabs, England) to the Apal/NotI digested pBI-CMV2 vector at insert/vector ratio of 3:1. Chemo-competent *Escherichia coli* DH5 $\alpha$  cells (New England Biolabs, England) were transformed with the ligated product. Seven colonies were amplified in LB (Luria-Bertani) liquid medium (Thermo Fischer Scientific, USA) and plasmids were purified with the QIAprep Spin Miniprep Kit (Qiagen, Switzerland). Digestion of positive clones with Apal and NotI (New

England Biolabs, England) was used to identify positive clones. For visualization, the digestion products were stained with ethidium bromide after gel electrophoresis on a 1% agarose gel. Clones with the correct insert gave band sizes of 2385 and 1803 bps. Using different forward and reverse primers (**Table 4**), the entire plasmid of one positive clone was sequenced using the 3130 Genetic Analyzer Sanger sequencer (Applied Biosystems, Switzerland). The newly designed reporter vector was called pRG13. The BKPyV Dunlop NCCR in the new designed reporter contained the 12-nucleotides sequence. All HPyVs NCCRs cloned in the pRG13 lack the 12-nucleotides sequence, hence the name pRG13D12. HPyV NCCRs lacking the 12-nucleotide sequences were synthesized (Eurogentec S.A, Belgium). The NCCRs were excised from the pUC57 vector using the restriction enzymes BssHII and MluI (New England Biolabs, England). Excised DNA products were visualized on 1% agarose gel and NCCR DNAs were purified with the nucleospin extract II columns. Next, the pRG13 reporter vector containing Dunlop NCCR cloned via BssHII and MluI restriction sites was digested with BssHII and MluI, and visualized on 1% agarose gel. The plasmid backbone fragment (3782 bps) was purified with the nucleospin extract II column. The concentrations of the purified DNA fragments (NCCR and plasmid backbone) were estimated using a NanoDrop 1000 spectrophotometer. The NCCR DNA fragments were ligated using T4 DNA ligase to the BssHII/MluI digested pRG13 vector at an insert/vector ratio of 3:1. Chemo-competent *Escherichia coli* DH5 $\alpha$  cells were then transformed with the ligated product. For each of the NCCR cloned, 10 colonies were PCR-screened with HPyV NCCR-specific reverse primers and a DsRed2 forward primer (Ds\_Red-F1) (**Table 5**). Colonies carrying the right inserts gave an approximate size of 700 bps. Using the 3130 Genetic Analyzer Sanger sequencer, two colonies with the right inserts were sequenced using HPyV NCCR-specific primers (**Table 5**). Colonies with the correct NCCR sequences was maximally amplified (maxi prep) in 400mL LB liquid medium. The plasmids were purified with the pure yield plasmid maxiprep System (Promega, Switzerland). The maxiprep plasmids were then re-sequenced.

**Fig. 13: Vector map of phRG.** The bi-directional reporter vector phRG recapitulating the HPyV genome contains the NCCR cloned via the MluI/BssHII sites in the forward orientation (as in the viral genome), dsRed2 as a marker of EVGR expression and EGFP as marker of LVGR expression. It also contains Beta globulin poly-adenylation signal for stabilizing the dsRed2 and EGFP messages, SV40 early promoter for driving

**Fig. 14: Vector map of pBI-CMV2.** The pBI-CMV2 vector contains a bi-directional CMV promoter, SV40 poly-adenylation signals for stabilizing messages, AcGFP reporter gene, Colicin E1 origin for bacteria replication and Ampicillin resistance gene for selection in bacteria.

Hygromycin gene, Hygromycin resistance gene for selection in eukaryotic cells, the ampicillin resistance gene for selection in bacteria and Colicin E1 origin for bacteria replication.

### Plasmid DNA Sequencing

Dye-terminator sequencing method was used to sequence plasmid DNA. Plasmid DNA was first PCR amplified to obtain sufficient amounts of template DNA concentration. Forward and reverse amplification was performed separately. For the sequencing PCR, a master mix of 4  $\mu\text{L}$  Big Dye vs. 3.1 (Applied Biosystem, Switzerland), 2  $\mu\text{L}$  5x buffer (applied Biosystem, Switzerland), 3.2  $\mu\text{L}$  primer for each forward and reverse reaction (final concentration of 160 nM) was used. 9.2  $\mu\text{L}$  of the master mix was pipetted into each PCR tube (Applied Biosystem, Switzerland). 400ng template DNA was added to the mix. The final volume was adjusted to 20 $\mu\text{L}$  with  $\text{H}_2\text{O}$ . Tubes were tightly closed with caps and transferred to the Veritti thermal cycler (Applied Biosystem, Switzerland). The PCR reaction was run with the program SEQAL:

94° C	5 min	} 35 cycles
96° C	30 sec	
55° C	15 sec	
60° C	4 min	
cooling at 10°C		

After the PCR reaction, the PCR product was purified with the NucleoSEQ columns (Macherey-Nagel, Switzerland) according to the manufacturer's protocol. In brief, the PCR sample was applied carefully in the center of the column and spin at 750x g in an Eppendorf tube to recover the purified samples. The purified sample was put in a 96-well plate (applied Biosystems, Switzerland), closed tightly with septum and put into the sequencing machine. The sequencing results were analyzed with SeqMan Pro software, version 14.0.0.

## 9 GLOSSARY

**Antibody:** A protein secreted by mainly plasma cells for the neutralization of foreign agents, such as bacteria and virus.

**Acute infection:** A relatively rapid disease onset, brief symptoms and disease cleared within days.

**Antigen:** Any foreign molecule that can induce an immune response, especially producing antibodies.

**B recognition element:** Is a cis-regulatory element immediately located upstream of TATA-box.

**Cancer:** Abnormal cell growth with the ability to spread or invade other compartment of the body.

**Capsid:** A protein shell for protecting a virus, consisting of small units called capsomeres

**Core promoter:** It is portion of the proximal sequence upstream of a gene harboring the transcriptional start sites (TSS). It also contains the following; regulatory factors, RNA polymerase binding motif and approximately –34 base pair upstream from the TSS.

**Core promoter elements:** These are sequence motifs such as initiation elements, TATA-box, downstream promoter elements (DPEs) and B recognition element (BRE) within the core promoter of a gene vital for gene transcription.

**Disease:** a disorder that affects part or the whole body of an organism associated with signs and symptoms.

**Deoxyribonucleic acid:** Is a macromolecule that contains the genetic information vital in the development, growth, reproduction and functioning of all living organisms including viruses.

**Downstream promoter element:** Is one of the core promoter elements vital for gene transcription by polymerase II, located downstream of the initiation element.

**Developmental or regulated promoter:** Is a promoter with a focused TSS, TATA-box or downstream promoter element and activated by a stimulus.

**Dyad symmetry:** These are two regions of a DNA sequence with inverted repeats of each other.

**Encapsidation:** It is a process of enclosing a viral genome in a capsid.

**ERAD pathway:** This is a cellular pathway targeting misfolded protein from endoplasmic reticulum for proteasomal degradation prior ubiquitination.

**Housekeeping or tissue-restricted promoter:** Is promoter with dispersed TSS, enriched with upstream BRE, contain CpG-island and constitutively active.

**Infection:** This is the invasion of the tissues of an organism by a disease-causing agent.

**Initiation element:** It is a core promoter element located downstream of a TATA box and upstream of a DPE, which initiate transcript even without a functioning TATA-box.

**Natural killer (NK) cells:** These are immune cells of the innate immune system exhibiting various activating and inhibitory surface receptors controlling their ability of kill target cells, activation and produce cytokines.

**Nuclear localization signals:** These are short amino acid sequences required for nuclear translocation of a protein.

**Open reading frame:** It is a continuous region of a codon with start and stop codons that can encode potential proteins.

**Palindrome sequence:** A sequence on DNA/RNA where a 5' to 3' forward sequence matches a sequence 5' to 3' reverse on a double helix.

**Pathogen:** A biological agent that can cause disease.

**Persistent infection:** This is a life-long infection which occurs when a primary infection cannot be cleared completely by the host immune system.

**Promoter:** DNA regions that control regulation and the initiation of transcription.

**Protein:** A biomolecule consisting of a chain or chains of amino acids.

**Ribonucleic acid:** It is a biomolecule with long chains of nucleotides for protein synthesis and containing genetic information like DNA.

**Recombination:** A process of recombining genetic material by genetic engineering.

**Seroprevalence:** Is the number of individuals in a population who are positive for a particular disease based on antibody presence in the blood against that specific disease.

**TATA-box:** It is an AT-rich sequence located in the promoter of genes upstream of the TSS.

**Transcription start site:** It is the region of the 3' end of a gene where transcription starts.

**Transcription factors:** These are proteins that regulate the rate of transcription of DNA to mRNA, by specifically binding to a recognition DNA sequence.

**Viral reactivation:** Active viral replication after a period of viral dormancy.

**Viremia:** Presence of viral DNA in the blood.

**Viruria:** Presence of viral DNA in the urine.

**Virus:** A small-infectious agent that can only replicate inside a living cell.

## 10 ACKNOWLEDGEMENTS

Firstly, I would like to thank Prof. Hans H. Hirsch who gave me the opportunity to do a PhD with him. More so, I am grateful for his scientific supports and supervision which has taught me a lot not only on scientific issues but also on social issues.

Secondly, sincere thanks go to my Faculty representative, Prof. Marcel Tanner and my co-referee Prof. Volker Thiel for being part of my PhD committee and for their scientific inputs during my committee meetings, and also Prof. Hans-Peter Beck for accepting to be the chair of my PhD defense.

I would like to thank all my colleagues for the helpful discussions during our lab meetings and of course the Norwegian research group of Prof. Rinaldo Christine for their nice discussions during our journal clubs, which has helped me a lot with respect to my scientific works.

Immerse thanks go to my wife Dr Nicole and her family for their supports throughout the period of my PhD. Special thanks go to my mom Grace for all the nice foods she sent from Cameroon to keep me strong and all my siblings back home especially Sylvester for their encouragements and of course my friends and relatives in Switzerland, Mathias, Calista, Clovis, Brenda, Vero, Nelvis for all the nice and relaxing moments.

Last but not the least, I thank the almighty God for the strength to accomplish this work.

## 11 CURRICULUM VITAE

Name: Ajuh Elvis Tasih  
Date and place of birth: Born 13. October 1986, in Cameroon  
Address: Schleifenbergstrasse 35, 4058 Basel  
Nationality: Cameroonian  
Marital status: Married  
Phone contact: +41779696222  
E-mail (personal): tasihe@yahoo.com  
E-mail (professional): [elvis.ajuh@unibas.ch](mailto:elvis.ajuh@unibas.ch)

### Educational qualifications

Oct. 2013-Sept. 2017 PhD in Microbiology, department of biomedicine, University of Basel, Switzerland  
Sept. 2011-Feb. 2013 Master of Science (MSc) in Infection Biology, Swiss Tropical and Public Health Institute (SwissTPH), University of Basel, Switzerland  
Sep. 2007- Jul. 2010 Bachelor of Science (BSc) in Microbiology, University of Buea, Cameroon  
2005-2007 G.C.E advanced level, Bilingual Grammar School Molyko, Buea, Cameroon  
2000-2005 G.C.E Ordinary level, Government Secondary School Bombe Bakundu, Cameroon

### Conferences presented

1. 25<sup>th</sup> annual meeting of the society for Virology, Bern Switzerland-Poster presentation
2. 74<sup>th</sup> annual meeting of Swiss Society for Microbiology-Bochum, Germany
3. 6<sup>th</sup> European Congress of Virology- Hamburg, Germany-Poster presentation
4. 1<sup>st</sup> Symposium of the Geneva Center for Emergence Viral Diseases-Geneva, Switzerland
5. Joint Annual Meeting SSM, SSI, SSHH, SSTMP, SSTTM, 2017, Basel, Switzerland-Poster presentation

### Publications

**Elvis T. Ajuh**, Tobias Bethge, Emma Kraus, Nicole Fischer, Fabian H. Weissbach, Rainer Gosert, Hans H. Hirsch\*. *Novel Human Polyomavirus non-coding control regions differ in bi-directional gene expression according to host cell, large T-antigen expression and clinically occurring rearrangements* (Manuscript under review).

Tobias Bethge, **Elvis T. Ajuh**, Hans H. Hirsch\* (2016) *Imperfect Symmetry of Sp1 and Core Promoter Sequences Regulates Early and Late Viral Gene Expression of the Bi-Directional BK Polyomavirus Non-Coding Control Region* J. Virol 90: 10101.

David C. Müller, Maarit Rämö, Christian Wetterauer, Valeria Perrina, Luca Quagliata, Tatjana Vlajnic, Christian Ruiz, Beate Balitzki, Rainer Grobholz, Rainer Gosert, **Elvis T. Ajuh**, Hans H. Hirsch, Lukas Bubendorf, Cyrill A. Rentsch. *Donor-derived, metastatic urothelial cancer after kidney transplantation associated with BK polyomavirus bearing a critical deletion in the viral non-coding control region* (Manuscript under revision).
