This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Modulation of the solubility of luminescent semiconductor nanocrystals through facile surface functionalization

Tomaso Avellini,\textsuperscript{a,b} Christophe Lincheneau,\textsuperscript{a} Marcello La Rosa,\textsuperscript{a} Antonio Pertegàs,\textsuperscript{c} Henk J. Bolink,\textsuperscript{c} Iain A. Wright,\textsuperscript{d} Edwin C. Constable,\textsuperscript{d} Serena Silvi,\textsuperscript{a} and Alberto Credi\textsuperscript{a,\*}

The solubility of luminescent quantum dots in solvents from hexane to water can be finely tuned by the choice of the counterions associated with carboxylate residues present on the nanocrystal surface. The resulting nanocrystals exhibit long term colloidal and chemical stability and maintain their photophysical properties.

Quantum dots (QDs) are semiconductor nanocrystals endowed with unique size-dependent optical and electronic properties\textsuperscript{1} and are emerging as substitutes for molecular fluorophores\textsuperscript{2} for applications in chemo/biosensing,\textsuperscript{3} medical diagnostics and therapy,\textsuperscript{4} light-emitting devices,\textsuperscript{5} and solar cells.\textsuperscript{6}

Despite recent progress in the preparation of high quality QDs in aqueous media,\textsuperscript{7} most reliable and widely used synthetic approaches are based on reactions performed in organic solvents.\textsuperscript{1} Such methods enable the preparation of QDs with accurate control of their size and properties and afford nanocrystals whose surface is coated with a layer of highly hydrophobic molecular ligands.\textsuperscript{8} These QDs are, therefore, (moderately) soluble only in apolar organic solvents such as toluene, hexane or chloroform. However, several applications – particularly, bioimaging and medical therapy – require that the nanocrystals are compatible with, and soluble in, aqueous media. Encapsulation of QDs with amphiphilic polymers\textsuperscript{9} results in stability in water and preserves the photophysical properties, but the increased diameter of the encased nanoparticles is a limitation for biological and FRET applications.\textsuperscript{10} Furthermore, utilization in optoelectronic devices requires that the QDs are soluble in suitable solvents for the deposition of homogeneous thin films, or that they are miscible with charge transporting host materials.

The control of the solubility of QDs in common solvents is crucial for viable processing of these nanomaterials. A frequently used methodology involves the replacement of the native capping ligands with other ligands that combine a surface anchoring unit with a functional (e.g., hydrophilic) module.\textsuperscript{11} Although exceptions exist,\textsuperscript{12} ligand-exchanged QDs usually exhibit a degradation of the photophysical properties and a poor long-term chemical and photochemical stability.\textsuperscript{13} Ligands with multiple thiol anchoring groups, such as dihydrolipoic acid (DHLA) and related compounds, have become increasingly popular, owing to their ability to form robust capping monolayers on the surface of metal and semiconductor nanocrystals.\textsuperscript{14} DHLA is obtained from lipoic acid (LA) upon reductive cleavage of the S–S bond of its 1,2-dithiolane moiety. While such a reaction occurs spontaneously in the presence of a noble metal surface, LA must be chemically reduced to DHLA\textsuperscript{15} or UV-irradiated\textsuperscript{16} prior to adsorption to semiconductor QDs.

Here we describe a general route for converting LA-based ligands to the active DHLA derivatives and using them to replace the native caps of QDs. The procedure enables the phase transfer of the nanocrystals in polar and aqueous media and, if LA is used as the capping agent, a facile adjustment of their solubility in a wide range of solvents.\textsuperscript{17}

The method relies on the use of a borohydride-loaded ion-exchange resin\textsuperscript{18} for the reduction of the 1,2-dithiolane, as shown in Scheme 1. The resin is commercially available or can be prepared by stirring an aqueous solution of NaBH\textsubscript{4} with an anion exchange resin (e.g., Amberlite\textsuperscript{R} IRA-400).\textsuperscript{19} In our case the resin contained typically 2.5 mmol of BH\textsubscript{4}\textsuperscript{-} per gram of polymer. The addition of the resin leads to a MeOH solution of lipoic acid (BH\textsubscript{4}/LA = 2:1) led, after 30 min stirring, to the conversion of LA to the DHLA\textsuperscript{15} anion (Scheme 1a). The process can be conveniently followed by absorption spectroscopy, monitoring the decrease of the disulfide band of lipoic acid at 330 nm. These measurements also suggest that DHLA is chemisorbed on the resin, most likely because of the interaction between the carboxylate and the ammonium moieties of the resin (Scheme 1a).
In order to extract the DHLA− species from the resin, we treated the beads with a MeOH solution containing an excess of a metal or ammonium salt (M′X−, Scheme 1b). The X− anion displaces DHLA− from the resin (which can be subsequently recovered), and a MeOH solution containing the active ligand as its M+ salt is obtained. It should be pointed out that the purification procedures usually carried out after the reduction of LA are not needed. At the end of the reaction, the excess reactant can be easily removed from the solution by decantation of the resin. The amount of DHLA just necessary for the cap exchange may be prepared, thus avoiding the storage of stock solutions of ligand under inert atmosphere at low temperature.

The cap exchange was performed by adding a hexane solution containing the hydrophobic QDs capped with trioctylphosphine (TOP) and trioctylphosphine oxide (TOPO) to the DHLA containing the hydrophobic QDs capped with trioctyl phosphine (TOP) with DHLA should be pointed out that the purification procedures be carried after the reduction of LA are not needed. At the end of the reaction, the excess reactant can be easily removed from the solution by decantation of the resin. The amount of DHLA just necessary for the cap exchange may be prepared, thus avoiding the storage of stock solutions of ligand under inert atmosphere at low temperature.

methanol was then evaporated under vacuum and the dried DHLA− Na+ QDs were dissolved in water and purified.

Typically, 5-10 μM aqueous solutions of DHLA Na+ capped nanocrystals of different structure and size were obtained, which resulted to be stable for at least 3 months. The minor shift in the absorption and emission peak wavelengths with respect to the starting QDs (Fig. 2) indicates that no aggregation takes place. In line with literature reports, CdSe cores were not emissive after phase transfer, whereas the luminescence efficiency of the final core-shell QDs in aqueous solution was 30-50% of that of the native hydrophobic nanoparticles.

![Fig. 1](image)

In this study, we report the synthesis of CdSe-5ZnS nanocrystals (d_{exc} = 3.6 nm) using NaOH as the M+ salt is obtained. It should be pointed out that the purification procedures usually carried out after the reduction of LA are not needed. At the end of the reaction, the excess reactant can be easily removed from the solution by decantation of the resin. The amount of DHLA just necessary for the cap exchange may be prepared, thus avoiding the storage of stock solutions of ligand under inert atmosphere at low temperature.

![Fig. 2](image)

Activation with the resin was also effective for a ligand comprising a 1,2-dithiolane moiety attached to a hydrophilic poly(ethylene glycol) domain (LA-PEG) and phase transfer of QDs was observed. In such a case the reduced DHLA-based ligand did not bind to the resin and the extraction step described in Scheme 1b was not necessary.

Interestingly, we found that the nature of the M′X− species not only plays the important role of extracting DHLA− from the resin (Scheme 1b) but also determines the solubility of the final QDs. We performed several cap exchange reactions following the above described route and using different metal or ammonium salts or hydroxides in place of NaOH. As shown in Table 1, QDs capped with the same ligand (DHLA−) and different cations exhibit remarkably different solubility properties. Counterion effects in nanocrystals capped with ionic ligands have been studied but, to our knowledge, this is the first investigation highlighting the role of counterions for adjusting the QD solubility in polar solvents. The spectroscopic properties of the nanocrystals are maintained in all the dispersions listed in Table 1, with absorption and emission peaks shifts not exceeding 5 nm in comparison to the native QDs. As an example, Fig. 3 shows photographs of QDs capped with DHLA TBA− in different solvents.

Although a rationalization of the pattern shown in Table 1 is not straightforward, the solubility of the DHLA M′ QDs in which M′ is an alkali cation or a quaternary ammonium ions with short alkyl substituents (e.g. TMA−) in methanol or water can be explained considering the large solvent enthalpies of these cations in these solvents. Tetraalkylammonium ions with longer chains render the QDs compatible with less polar organic solvents, owing to Van der Waals forces between the solvent molecules and the alkyl chains. Other effects can be relevant in specific cases: for example, favorable
cation-π interactions of lithium ions with aromatic solvent molecules may explain why DHLA-Li QDs are soluble in toluene. It is noteworthy that TBA+ ions provide solubility of the anionic nanocrystals in a large variety of solvents (Table 1), suggesting that such cations can afford a good compromise in terms of lattice and solvation energies in media as different as chloroform and water.

In summary, we have developed a simple method for the chemical activation of ligands based on the 1,2-dithiolane unit and their utilization for exchanging the native capping ligands of QDs. If the ligand is lipic acid, the procedure enables the precise modulation of the QD solubility in a wide range of solvents with different polarity (from hexane to water). The final nanocrystals maintain their spectroscopic properties and exhibit long term colloidal and chemical stability. Indeed, the development of viable routes to program the solubility of QDs in common solvents without degrading their physical properties is an important requirement to foster the technological exploitation of these nanomaterials.
