ABSTRACT: The Pt(bodipy)–(mercaptopyrene) dyad BPTSPyr shows four different emissions: Intense near-infrared phosphorescence ($\Phi_{ph}$ up to 15%) from a charge-transfer state pyrS$^\cdot$$\rightarrow$Pt–BDP$^\cdot$, additional fluorescence and phosphorescence emissions from the 1ππ$^*$ and 3ππ$^*$ states of the bodipy ligand at r. t., and phosphorescence from the pyrene 3ππ$^*$ and the bodipy 3ππ$^*$ states in a glassy matrix at 77 K. In accordance with Kasha’s rule, the vast majority of compounds emits solely from their lowest excited electronic state. Dual fluorescence and phosphorescence emissions may, however, be observed if intersystem crossing (ISC) occurs at a competitive timescale to fluorescence and if the rate constant for phosphorescence emission is increased by a proximal heavy atom with a large spin-orbit coupling constant. By capitalizing on this remote heavy-atom effect we and others have recently observed dual fluorescence and phosphorescence emissions at r. t. from metal complexes with a σ-bonded or remotely attached bodipy (BDP) ligand. Multiple emissions from a single compound can also result from inefficient Förster resonance energy transfer in dyads with two electronically decoupled, orthogonally aligned chromophores. Intriguing examples are multiply emissive Ir(ppy)$_2$(Q) complexes with two cyclometalated phenylpyridine (ppy) and a 2-hydroxyquinoline ligand Q, which show ligand-localized fluorescence from 1nπ$^*$ and phosphorescence from 3MLCT (MLCT = metal-ligand charge-transfer) states of the different ligands. We report here on the new meso-Pt bodipy complex BPTSPyr (Scheme 1), which combines the above principles and presents four different emissions owing to the coexistence of energetically close-lying ligand-localized and charge-separated excited states.

BPTSPyr was synthesized from trans-Pt(bodipy)(PET$_3$)$_2$. BPTI$^7$ by halogenide abstraction with AgOTf and subsequent addition to a solution of deprotonated 1- mercaptopyrene (pyrS). The same protocol was also used to prepare the complex

*Excitation wavelength in nm. ¥Wavelength of the fluorescence (fl) or phosphorescence (ph) emissions in nm. ¥Phosphorescence quantum yield. ¥Lifetime of the phosphorescence emissions. ¥Lifetime of the CT emission. ¥Measured in a 2-MeTHF glass at 77 K, $T_{0} = 3.70 \pm 0.2$ ns.

Importantly, and in contrast to MesPSPyr, BPsPyr exhibits four different emissions depending on excitation wavelength, solvent polarity, and temperature (Fig. 2). As shown in Fig. 2a, excitation into the PB-CT absorption band at 520 nm leads to broad and unstructured NIR emission with a quantum yield of 8% in toluene. The emission shifts red with increasing solvent polarity, from 724 nm in toluene to 784 nm in THF and to 816 nm in acetone (Table 1). Its strong solvatochromism and the lifetime of 6.7 μs in toluene (for lifetime decays see Fig. S28-S30, ESI†) indicate that this emission emanates from the $^{3}$PB-CT state. We note that heavy atom-free donor-stabilized BDPs were also shown to undergo efficient ISC to the T₁ state via an excited CT state; the latter systems are, however, non-phosphorescent.$^{18-20}$

Excitation into the BDP $nπ^{*}$ absorption band at 470 nm (Figs 2b and S31, ESI†) opens two further radiative pathways: BDP-based fluorescence at 484 nm and phosphorescence at 635 nm are observed in addition to the $^{3}$PB-CT emission. Changing the solvent from toluene to THF or acetone increases the energy separation between BDP $nπ^{*}$ and the $^{3}$PB-CT states and allows for tuning of the emission color from red in toluene (CIE coordinates 0.6052/0.3211 in THF) to almost white in THF (CIE coordinates: 0.2209/0.3206) or acetone (CIE coordinates 0.3357/0.2901). Concomitantly with its red-shift the lifetime of the $^{3}$PB-CT emission decreases from 6.7 μs in toluene solution to only 2.4 ns in acetone (Fig. S30a, ESI†). This in turn increases the intensity ratio of the $nπ^{*}$/CT$^{*}$ to the $^{3}$PB-CT emissions (Fig. 2b). We note that the BDP-based emissions of BPsPyr are not due to contamination with the BPTI precursor (Fig. S32, ESI†).

Triple emission upon excitation into the BDP $nπ^{*}$ band at 470 nm indicates that ISC from the $nπ^{*}$ to the $nπ^{*}$ state of the BDP ligand as well as formation of the $^{3}$PB-CT state and subsequent ISC to the $^{3}$PB-CT state occur at similar rates as fluorescence from the $^{3}$PB-CT state. When the sample is excited into the pyr$S$ $nπ^{*}$ band at 415 nm, again solely $^{3}$PB-CT emission is observed, but with an even increased quantum yield of 15% ($\lambda_{exc} = 420$ nm) as compared to 8% for $\lambda_{exc} = 520$ nm (Fig. 2a,c), rendering BPsPyr a powerful NIR emitter. All the above
conclusions are fully supported by excitation vs. emission maps and excitation spectra (Fig. S33, S34, ESI†).

Emission spectra recorded in a glassy Me-THF matrix at 77 K show only two features, irrespective of the excitation wavelength: the $^3\pi\pi^*$ BDP emission with a maximum at 635 nm and a typical lifetime of 279 μs (Fig. S35, ESI†) as well as a structured emission enveloping the region in from 649 to 750 nm (Fig. 2d). This latter feature and its lifetime of 1.12 ms (Fig. S35, ESI†) are typical of a pyrene-based $^3\pi\pi^*$ emission.5, 16, 17

The $^3\pi\pi^*$ excited states of the BDP and pyrS ligands are hence both accessible from excitation into any band in the rigid matrix. This indicates that, at 77 K, population of the close-lying BDP and pyrS $^3\pi\pi^*$ from the $^3\Pi$-CT state of BPtSPyr is more rapid than direct intersystem crossing to the $^3\Pi$-CT state and that deactivation to the $^3\Pi$-CT state is blocked under these conditions. One possible explanation is that the $^3\Pi$-CT and $^3\Pi$-CT states possess very similar nuclear coordinates and the BDP and pyrS $^3\pi\pi^*$ potential wells have more easily accessible intersections with the $^3\Pi$-CT potential well. Previous studies have similarly demonstrated direct singlet-to-triplet electron-transfer by spin-orbit coupling.21-23

The Jablonski diagram of Scheme 2 summarizes the processes following the different excitations of BPtSPyr. Electronic decoupling of the pyrS- and the BDP-localized $^1\pi\pi^*$ states, as indicated by the confinement of the HOMO to the pyrS of and of the LUMO to the BDP ligand (Fig. S26, ESI†), explains the absence of pyrS to BDP energy transfer from the pyrene-based $^1\pi\pi^*$ state $S_1$ and of any BDP emission after excitation into the pyrS $^1\pi\pi^*$ band at 415 nm. The BDP-based $^1\pi\pi^*$ and $^3\pi\pi^*$ states $S_3$ and $T_3$ are thus exclusively populated by excitation into the BDP $^1\pi\pi^*$ band. In contrast, the $^3\Pi$-CT state, which constitutes the energetically lowest excited triplet state $T_1$, is accessible from all three excited singlet states, either via IC to the $^3\Pi$-CT and subsequent ISC, or via ISC and subsequent electron transfer from the higher-lying pyrS-based $T_2$ and BDP-based $T_3$ states (note that MesPtSPyr also undergoes ISC from the pyrene-based $^1\pi\pi^*$ state). At 77 K, direct singlet to triplet electron-transfer from the $^3\Pi$-CT state allows population of the pyrS- and BDP-based triplet states $T_2$ and $T_3$ (blue arrows in Scheme 2) and renders the pyrS-based phosphorescence emission observable, which, at r.t., is quenched by rapid decay into the lower-lying $^3\Pi$-CT state.

The proposed excited state cascade is further supported by transient absorption (TA) spectroscopy in THF. TA spectra recorded over the first 200 ns after excitation are very similar to each other, irrespective of whether the sample is excited at 410 (pyrS), 470 (BDP), or 532 nm (PB-CT absorption) (Fig. 3 and Fig. S36, ESI†). Three main features are observed: The bleached pyrS and BDP ground state absorption signals at ca. 400 nm or 470 nm, and an excited state absorption (ESA) signal at 550 nm, which we assign to the pyrS$^{3}\pi\pi^*$ radical cation (vide infra). Identical monoexponential kinetics with a common time constant of 50 ns were found for all three transients when excited at 532 nm (for single point kinetics for each TA feature see Fig. S37a, ESI†). When excited into the BDP absorption at 470 nm the features at 415 nm and 550 nm still have a time constant of 50 ns, but the bleach recovery at 475 nm has much longer kinetics of 16.5 μs in THF. This is in accordance with the long-lived BDP $^3\pi\pi^*$ excited state in that solvent (red trace in Fig. S37a, ESI†). Transient absorption bleach recoveries and decays match the luminescence lifetimes in all cases. This corroborates that none of the observable emissions originate from impurities but represent inherent photoluminescence from BPtSPyr.

The common CT state after excitation should exhibit spectroscopic features similar to the oxidized and reduced forms of BPtSPyr. Cyclic voltammograms show a reversible oxidation at +0.18 V and a reduction at -1.97 V against the ferrocene/ferrocinium couple (Fig. S39 and Table S3, ESI†). This allowed us to experimentally probe the UV/Vis/NIR features of the oxidized and reduced forms of BPtSPyr by means of
spectroelectrochemistry. Upon oxidation, the pyrS-based ππ* absorption band bleaches while the BDP ππ* band exhibits an only minor red-shift of 316 cm⁻¹ (Fig. 4). Based on literature data²⁴,²⁵ and the results of our TD-DFT calculations (Fig. S40 and Table S4, ESI†), the new absorption bands at ca. 520, 550, 750, and 1000 nm can be assigned to ππ* transitions of the pyrS** radical cation. When BpTSpyr is reduced, the BDP ππ* and the PB-CT absorption bands bleach while the pyrS-based ππ* band experiences a moderate red-shift. The weak new band at 518 nm constitutes a main ππ* transition of the BDP ligand (Fig. S41 and S42, Table S5, ESI†); it is essentially identical in shape and energy to that observed for BpTpt²⁹. Calculated spin densities for the BpTSpyr radical cation and anion also agree with a pyrS-based oxidation and a BDP-based reduction (Fig. 5 and Table S6, ESI†). The results of our spectroelectrochemical experiments and our calculations thus confirm our assignment of the ESA signal to the pyrS** constituent as well as the character of the HOMO and LUMO of BpTSpyr.

In summary, the BpTSpyr dyad combines several remarkable features. It constitutes an extremely rare case of a compound showing emissions from four different excited states and acts as a powerful NIR emitter. Its emission profiles and colour can be tuned by the excitation wavelength and solvent polarity from deep red to almost white. The crucial role of the pyrS**–Pt-BDP** charge-transfer state within the excited state cascade was identified by TA spectroscopy, spectroelectrochemical methods and TD-DFT calculations.
