1 ZUSAMMENFASSUNG FÜR LAIEN

Konventionelle medikamentöse Therapien basieren auf der Verabreichung therapeutischer Moleküle über verschiedene Verabreichungswege (z.B. orale, parenterale oder topische Verabreichung). Alle diese Routen haben eine Gemeinsamkeit: Durch die Verabreichung wird der ganze Organismus dem therapeutischen Molekül ausgesetzt. Dies führt dazu, dass diese Moleküle auch mit Zellen und Geweben interagieren, mit denen sie nicht interagieren sollten. Dies ist einer der Hauptgründe für beobachtete Nebenwirkungen. Um die notwendige Konzentration am Wirkort zu erreichen wird daher eine viel höhere Dosis als nötig verabreicht, da die verabreichte Dosis sich im Körper verteilt.

Eine Lösung dieses Problems besteht darin, die therapeutischen Moleküle direkt zu ihrem Wirkort zu führen. Einerseits führt dieser Ansatz - in Fachkreisen "targeted drug delivery" genannt - dazu, dass weniger Moleküle am falschen Ort landen, was Nebenwirkungen bereits reduzieren kann. Andererseits kann durch diesen Ansatz die Dosis, die verabreicht werden muss, bei gleichbleibender Wirkung drastisch reduziert werden, weil die Moleküle direkt zum Wirkort geführt und nicht auf den ganzen Körper verteilt werden. Verschiedene Strategien ermöglichen die gezielte Verabreichung von therapeutischen Molekülen, doch die am weitesten verbreitete Strategie basiert auf der Verwendung von Nanopartikeln. Aufgrund ihrer extrem kleinen Grösse (≤ 100 nm) können diese Nanopartikel von Zellen aufgenommen werden und ermöglichen dadurch die intrazelluläre Freisetzung der therapeutischen Moleküle. Unter den verschiedenen Typen von synthetischen (nicht-viralen) Nanopartikeln sind lipidbasierte Nanopartikel die am besten charakterisierten und am weitesten verbreiteten Systeme. Nanopartikel werden in der Regel zusätzlich dekoriert mit Molekülen, die eine lange Zirkulation im Blutkreislauf ermöglichen, sowie mit sogenannten targeting Molekülen, die eine gezielte Verabreichung erst ermöglichen und die

Nanopartikel zu spezifischen Zellpopulationen führen.

Die Verkapselung innerhalb von Nanopartikeln ist besonders wichtig für therapeutische Nukleinsäuren (z.B. DNA), da nackte Nukleinsäuren in der Blutbahn umgehend von Serumnukleasen abgebaut werden. Dies kann durch Verkapselung verhindert werden. Die Verabreichung therapeutischer Geninformation (Gentherapie) zeigt dabei einige Vorteile gegenüber konventionellen medikamentösen Therapien. Viele genetische Erkrankungen manifestieren sich aufgrund eines Defekts in der genetischen Information, die als Blaupause für die Herstellung von Enzymen dient, welche wiederum für die Aufrechterhaltung der normalen Körperfunktionen verantwortlich sind. Aufgrund des Defekts in der Blaupause können die entsprechenden Enzyme nicht oder nur in einer Form mit reduzierter Enzymaktivität hergestellt werden. Wird der Zelle jedoch die korrekte Geninformation (z.B. in Form von DNA) zugeführt, können die negativen Einflüsse des defekten nativen Enzyms ausgeglichen werden. Die folgenden Vorteile treten daher besonders zutage: Erstens ist die konventionelle medikamentöse Therapie oftmals nicht in der Lage, die Ursachen der Erkrankung zu beheben, sondern behandelt nur die Symptome. Zweitens kann eine Zelle, wenn mit der korrekten Blaupause versorgt, das Enzym selber herstellen. Drittens wurde für einige genetische Erkrankungen gezeigt, dass schon Bruchteile der natürlichen Aktivität eines Enzyms ausreichen, damit betroffene Personen symptomfrei leben können. Viertens sorgt die lange Persistenz von DNA im Zellkern dazu, dass die Anzahl therapeutischer Interventionen massiv reduziert werden kann (z.B. halbjährliche Intervention gegenüber täglicher).

Trotz dieser Vorteile bleibt dieses Forschungsgebiet ein komplexes Thema und viele der zugrunde liegenden Mechanismen entziehen sich bisher unserer Kenntnis. Aus diesem Grund ist es das Ziel des ersten Teils der vorliegenden Doktorarbeit, die Effizienz einer klinisch relevanten Nanopartikelformulierung zu erhöhen und das Verständnis molekularer Strukturen für eine erfolgreiche

Gentherapie zu vertiefen. Weiter zeigt die Arbeit im zweiten Teil Möglichkeiten auf, wie man die molekularen Wechselwirkungen zwischen DNA und Nanopartikeln mittels einer fluoreszenzbasierten Methode bestimmen kann. Im Dritten Teil geht die Arbeit auf die Möglichkeit ein, virale Strukturen als targeting Moleküle auszunutzen und wie eine lange Zirkulationszeit im Blutkreislauf erreicht werden kann, ohne eine Immunantwort zu provozieren.

Im letzten Teil wird ein neues Tiermodell präsentiert und diskutiert. Das Tiermodell bedient sich der Embryos des Zebrafisches, um neue antibiotische Substanzen und neue Therapieansätze zu testen. Aufgrund ihrer Transparenz können fluoreszenzbasierte Methoden verwendet werden und die hohe Reproduktionsrate ermöglicht einen hohen experimentellen Durchsatz bei der Suche nach neuen antibiotischen Substanzen.

2 SUMMARY

Conventional drug therapy relies on the introduction of therapeutic molecules into the body through various routes of administration (*e.g.*, oral, parenteral, or topical). However, all these applications share a serious drawback: Following administration, the whole organism is exposed to the therapeutic molecule. Consequently, therapeutic molecules can interact with cells or tissues they were not intended to interact with, which is a major driver of side effects. To account for the distribution in the body, much higher doses than necessary are administered to ensure a sufficiently high concentration of the therapeutic molecule at the target site.

A solution to this problem is to direct the therapeutic molecules to the specific cells where they are needed. On the one hand, this approach, called targeted drug delivery, reduces the number of molecules that end up in the wrong place in the body, thereby reducing side effects. On the other hand, this enables a drastic reduction of the required dose while maintaining the same effect because the therapeutic molecules are directed to the site where they are required instead of being distributed all across the body. There are several strategies to achieve targeted drug delivery but the use of nanoparticles is one of the most common approaches. Due to their small size (≤ 100 nm), nanoparticles are taken up by cells and therefore, enable the intracellular release of therapeutic molecules. Among the different types of nanoparticles of synthetic (non-viral) origin, lipid-based nanoparticles are the best characterized and most used ones. Nanoparticles are usually decorated with molecules that enable prolonged circulation in the bloodstream and with targeting molecules that direct the nanoparticle to a specific cell population.

The benefits offered by encapsulation into targeted nanoparticles are even more pronounced for nucleic acids (*e.g.*, DNA) because naked nucleic acids are rapidly degraded in the blood circulation by serum nucleases which is pre-

vented by encapsulation. Gene therapy offers a number of advantages. Many genetic diseases manifest due to defects in the genetic information that is the blueprint for enzymes responsible for maintenance of normal body functions. Due to the defect in the blueprint, the enzyme cannot be produced or its activity is reduced. The introduction of the correct genetic information (blueprint) in the form of DNA or other nucleic acids can counterbalance the negative effects of the defective native enzyme. This approach is very attractive due to several reasons: First, conventional drug therapy is usually unable to cure genetic diseases but only treats or attenuates the symptoms. Second, with the correct blueprint at hand, the cells own "enzyme factory" can produce the "cure". Third, the restoration of only a small proportion of the native activity of the enzyme is often sufficient for the patients to live without symptoms. Fourth, the long persistence of DNA molecules in the cell nucleus ensures prolonged expression of the enzyme, thereby drastically reducing the number of therapeutic interventions compared to conventional drug therapy (*e.g.*, once every six months compared to daily intake).

Despite these promises, the field of non-viral drug and gene delivery is a very complex topic and the underlying mechanisms and important factors for therapeutic success often remain elusive. Therefore, the first part of this PhD thesis aimed to improve the efficiency of a clinically relevant lipid nanoparticle formulation for gene delivery, as well as our understanding of molecular structures important for successful gene delivery (Chapter 1). Furthermore, the interactions between lipid nanoparticles and DNA molecules are investigated using a fluorescence-based method. The method provides a means to determine the number of DNA molecules per nanoparticle, a question that has only been addressed theoretically so far (Chapter 2). The proposed method enables researchers to draw more precise conclusions from their gene delivery experiments. The third part of the thesis focuses on the improvement of targeting and

blood circulation properties of lipid-based drug delivery vehicles. A novel targeting molecule derived from the hepatitis B virus enables highly efficient and selective liposome delivery to hepatocytes whereas a novel nanoparticle shielding molecule demonstrated enhanced blood circulation properties comparable to the gold standard (PEG) while avoiding immune responses associated with PEG (Chapter 3).

Finally, a transparent animal infection model (zebrafish embryo) for the investigation of novel antibiotic compounds is discussed (Chapter 4). The transparency allows the application of fluorescence-based methods to evaluate antibiotic compounds, thereby improving our understanding of antibiotic therapy according to the proverb "seeing is believing". Furthermore, the high reproduction rate and the relatively low regulatory requirements enable the screening of a large number of compounds, thereby possibly accelerating research in the field of antibacterial drug therapy.

3 INTRODUCTION

3.1 THE GOALS OF GENE DELIVERY

The delivery of therapeutic nucleic acids is a promising strategy to treat or even cure inherited genetic diseases and possibly also acquired diseases. In fact, many inherited genetic diseases such as severe-combined immunodeficiency (SCID), haemophilia, Crigler-Najjar syndrome, Gilbert's syndrome, Niemann-Pick disease, or α 1-antitrypsin deficiency [1–7] are associated with genetic defects leading to loss of function of proteins or very low levels of enzyme activity. Using gene therapy, several approaches can be envisioned to treat such conditions. First, small interfering RNA (siRNA) can be introduced into cells to modify or inhibit the protein expression level by means of RNA interference (RNAi). [8] As a double-stranded oligonucleotide of around 19-25 base pairs in length, siRNA binds to the RNA-induced silencing complex (RISC), allowing the cleavage of the targeted messenger RNA (mRNA) thereby inhibiting translation of the targeted mRNA into proteins. [9] Another approach is the introduction of genetic material (*e.g.*, plasmid DNA) encoding for a functional version of the protein. With the correct blueprint for the protein provided in the form of RNA or DNA, the cells' own (transcription)/translation machinery is then capable to produce the functional variant of the dysfunctional protein. In some cases (*e.g.*, cystic fibrosis) such interventions seem very promising due to the fact that only a small fraction ($\leq 10\%$) of the native enzyme activity needs to be restored for the affected patients to live symptom-free. [10] Moreover, the transient nature of this gene delivery approach circumvents issues associated with gene therapies relying on insertion of the delivered DNA into the host cell's genome. Generally, plasmid DNA exists as an episomal entity that is not integrated into host chromosomal DNA and replicated separately, [11,12] although plasmid DNA can also be designed to promote chromosomal integra-

tion. [13, 14] The third possible intervention is relying on gene editing. Genetic information *e.g.*, plasmid DNA encoding for gene editing tools such as CRISPR/Cas9 can be introduced using gene delivery systems to modify the target cell's genome. Gene editing holds the promise to cure genetic diseases on a genomic level but is also associated with more severe ethical concerns compared to transient gene delivery due to the long-term implications of insertion of exogenous genetic material into the genome. [15]

3.2 STRATEGIES TO DELIVERY GENETIC MATERIAL

Nucleic acids (such as DNA, or especially RNA) are unstable in the blood circulation when injected intravenously [16, 17] and need to be protected from noxious agents such as serum nucleases. An attractive approach to protect nucleic acids relies on encapsulation of the nucleic acids into nanocarriers that mimic viral structures. In the field of gene delivery, we can identify several nanocarrier-based delivery strategies (in contrast to physical methods such as microinjection or electroporation, which offer no protection because these are not carrier-based approaches):

As a result of millions of years of evolution, viruses represent a naturally evolved vector that is able to transfer exogenous nucleic acids (DNA, RNA) to human (or other) cells in a very efficient manner. [18] It is therefore not surprising that gene therapy was pioneered by viral carriers due to these properties since the advent of this therapeutic option. Despite their efficiency, viral vectors carry several drawbacks such as immunogenicity, high costs, oncogenicity and the risk for insertional mutagenesis, as well as the limited size of DNA that can be encapsulated by viruses. [19, 20]

As an alternative to viral vectors, synthetic non-viral nanoparticulate drug delivery systems can be used to encapsulate therapeutic agents. Non-viral

delivery vehicles can be divided into inorganic materials, polymeric materials, and lipid or lipid-like materials. While inorganic materials were the first non-viral gene delivery vehicles to be discovered, [21] they are often only suitable for *in vitro* experiments. Polymeric materials are very versatile, allow for targeting approaches and efficiently condense DNA into nanoparticles but have their drawbacks in their high batch-to-batch variability and cytotoxicity. For polymeric compounds, it is key to find the balance between efficiency and cytotoxicity. For example, it was reported that both delivery efficiency and cytotoxicity increase with polymer length. [19] Finally, lipid-based non-viral gene delivery systems are the most thoroughly investigated non-viral gene delivery systems, [22] show low immunogenicity and toxicity, [23] allow for targeting approaches, and can incorporate large nucleic acid molecules. While lipid based systems are probably the best of the “artificial” transfection systems, they also suffer from some drawbacks such as higher cytotoxicity than viral vectors, [24] a possible colloidal instability in biologically relevant media, [25–27] rapid clearance from the blood compartment due to unspecific interactions with membranes or serum proteins when unshielded, [28] and a general lack of efficiency and specificity compared to viral vectors. [29, 30] However, there are several approaches to tackle the drawbacks of lipid-based gene delivery vehicles as discussed later on. For example, surface modification of the nanoparticles with sterically hindering and hydrophilic polymeric compounds such as polyethylene glycol (PEG) increases colloidal stability and reduces clearance of lipid-based nanoparticulate gene delivery systems when they are administered intravenously, while the use of targeting moieties increases efficiency and specificity. Due to the aforementioned advantages and the presented strategies to circumvent drawbacks of lipid-based gene delivery systems, this thesis focuses on liposomes and lipid nanoparticles. Different lipid-based non-viral gene delivery vehicles and the most important influence

factors for gene delivery are discussed in detail in **Chapter 1.1**, [31] while a straightforward one-pot synthesis to obtain aminolipids for lipid-based gene delivery is described in **Chapter 1.2**. [32] The proposed synthesis described in this thesis is in stark contrast to many other described syntheses in that it comprises a one-pot reaction as opposed to complicated multi-step reactions often seen in literature. [33,34] Moreover, avoidance of a cationic charge can circumvent cytotoxicity issues because interactions between the cationic lipid and cellular proteins, membranes and serum proteins can account for cytotoxicity, inflammatory toxicity, reduced cellular uptake, accelerated blood clearance, or even hemolysis [24,35]

3.3 NUCLEIC ACIDS FOR GENE DELIVERY

In addition to the composition of the nanoparticle, the type of nucleic acids used to carry the genetic information of interest can influence the interaction with the gene delivery system [36,37] and thereby the outcome of the experiment or therapy. For example, RNA moieties do not need to be delivered to the nucleus and offer pharmacological effects without nuclear entry, which is an important hurdle in DNA delivery. Thus, it is sufficient to deliver RNA moieties to the cytosol where they can either be translated into proteins (mRNA) or inhibit or modify protein expression by a process called RNA interference (siRNA). Plasmid DNA, however, needs to be translocated to the nucleus to be transcribed and translated into proteins. Despite the additional hurdle of having to enter the cell nucleus, plasmid DNA is able to introduce the genetic blueprint for the prolonged expression of therapeutic proteins (up to several months). In stark contrast, these effects are short-lived in the case of RNA-based strategies. [37,38] In view of this, plasmid DNA-based strategies seem to be beneficial when the long-term expression of a protein is desired because

the number of administrations can be reduced, resulting in increased compliance. However, due to their bacterial origin, plasmids contain sequences not necessary for, or even detrimental to, successful gene delivery. In addition to the expression cassette, which contains the gene of interest (GOI) as well as an eukaryotic promoter and a polyadenylation (polyA) sequence, plasmid DNA also comprises a bacterial backbone including a bacterial origin of replication (ORI), and antibiotic resistance genes. [11,39] This bacterial backbone can be recognized by the immune system and is subjected to epigenetic silencing, leading to a complete loss of expression of the desired protein in the long-term. [39–41] To reduce or even eliminate this time-dependent epigenetic silencing, a miniaturized plasmid moiety was proposed: minicircle DNA. Minicircle DNA is devoid of bacterial backbone sequences and is therefore both, smaller in size and less prone to epigenetic silencing. [42] This results in increased delivery efficiency and transgene expression levels, as well as in a prolonged transgene expression. For example, long-term treatment of murine phenylketonuria with minicircle DNA encoding for murine phenylalanine hydroxylase led to a normalized blood phenylalanine level and reversed hypopigmentation for more than 1 year, whereas phenylalanine clearance rapidly declined after treatment with the corresponding parental plasmid. [43] There is a consensus in the literature that minicircle DNA is superior to its corresponding larger parental plasmid DNA. However, the implications for the formation of nanoparticle/minicircle DNA complexes are still a matter of debate. To improve the understanding of the interactions between nanoparticles and different DNA molecules, a straightforward, fluorescence-based method (fluorescence cross-correlation spectroscopy, FCCS) is discussed in **Chapter 2.1**. [44] Because confocal imaging is a standard method for the assessment of gene delivery efficiency, many laboratories in principle possess the capability to perform FCCS experiments. Therefore, this method can be used to gather

additional information on the formation of nanoparticle/DNA complexes and to improve the quality of conclusions drawn from transfection experiments.

3.4 TARGETING OF GENE DELIVERY VEHICLES

The delivery of therapeutic agents to specific cell populations or tissues has been the goal of targeted drug delivery approaches for a long time. [45, 46] Therapeutic agents other than nucleic acids that also profit from a targeted drug delivery approach include, but are not limited to, small molecules, [47] and large biomolecules such as enzymes. [48, 49] Targeting of therapeutic agents can be achieved by several ways, for example by direct coupling of a targeting moiety to the therapeutic agent or by encapsulation of the therapeutic agent into a nanocarrier vehicle and subsequent modification of the vehicle with targeting moieties. [48] While direct coupling of targeting moieties to the therapeutic agent can be an attractive approach for large but stable biomolecules, encapsulation into nanocarriers is the preferred option for small molecules or nucleic acids. Moieties suitable for targeting include for example small molecules, [50, 51] sugars, [52, 53] peptides, [54, 55] non-immune proteins, [56–59] or antibodies or fragments thereof. [60–62] An interesting approach is to exploit naturally occurring mechanisms for selective targeting strategies such as mechanisms used by pathogens. An example of such a mechanism is provided by the hepatitis B virus (HBV). It was shown that less than 10 virus particles are sufficient to induce a pathogenic HBV infection in chimpanzees. [63] The large HBV envelope protein (HBVpreS) was shown to contain a highly specific amino acid sequence responsible for the efficient and specific targeting of hepatocytes. [64, 65] The applicability of this approach to specifically target hepatocytes using HBVpreS peptide variants as a targeting moiety is discussed in **Chapter 3.1**. [66]

3.5 AVOIDING RECOGNITION BY THE IMMUNE SYSTEM

For successful targeting strategies, it is important to optimize the circulation behavior of nanoparticles. Unshielded nanoparticles are prone to unspecific interactions with *e.g.*, cell membranes or serum proteins [28, 67, 68] due to charge interactions. Such interactions lead to opsonization of the nanoparticle surface and aggregation of nanoparticles due to impaired colloidal stability. Large aggregates or opsonized nanoparticles are then rapidly cleared *e.g.*, by macrophages of the mononuclear phagocytic system (MPS), also called the reticuloendothelial system (RES). [69–71] To avoid opsonization and clearance from the blood circulation, decoration of nanoparticles with PEG (*e.g.*, using 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[methoxy(polyethylene glycol)-2000], DSPE-mPEG2k) turned out to be the gold standard since 1990. [72–76] However, despite improved circulation properties offered by PEGylation, the emergence of Anti-PEG antibodies has raised concerns towards this strategy. It is believed that increased exposure to PEG, which is contained in many products (such as cosmetics) that are used in everyday life, is at least in part responsible for the emergence of Anti-PEG antibodies even in healthy individuals. [77] The emergence of Anti-PEG antibodies is especially detrimental to therapeutic interventions that require repeated dose administration of PEGylated moieties due to the drop in efficiency observed for the second and following interventions. [78–81] Because both, the phospholipid that anchors PEG in the nanoparticle and PEG itself are considered to cause immune reactions, [82] it is not sufficient to replace only the hydrophilic part of DSPE-mPEG2k but a replacement of the anchor is also needed. As a superior alternative to DSPE-mPEG2k, the use of bisalkyl polysarcosines (BA-pSar), where the DSPE anchor is replaced by bisalkyl chains and the mPEG2k moiety is

replaced by polysarcosines is discussed in **Chapter 3.2**. [83]

3.6 *In Vivo* ASSESSMENT OF NANOPARTICULATE DRUG DELIVERY VEHICLES AND SMALL MOLECULE DRUGS

The assessment of the circulation behavior of BA-pSar-modified liposomes and of HBVpreS-modified liposomes was carried out in the zebrafish (*Danio rerio*) embryo animal model in these studies. The zebrafish embryo is a fast-reproducing organism that allows for high-throughput screenings in a vertebrate animal model. Its transparency makes it especially suitable for fluorescence-based methods thereby providing qualitative data with respect to circulation behavior or macrophage clearance. There is a large variety of genetic variants of zebrafish that express different fluorescent proteins in different tissues, for example the kdrl:eGFP (fluorescent vasculature) or the mpeg:kaede (fluorescent macrophages) fish lines. Another important consideration in animal trials is the administrative effort required to rectify animal experiments. The zebrafish embryo is classified as cell culture trial up to 5 days (120 h) post-fertilization, [84] avoiding the need for approval of animal trials and thereby increasing the possible experimental throughput as well. Moreover, assessments in the zebrafish embryo model, implemented in our lab by excellent work of Dr. Sandro Sieber, were shown to be highly predictive of the situation in rodents (mice, rats). [85] Consequently, the zebrafish embryo offers the unique possibility to pre-select interesting candidates for animal trials and discard candidates with poor circulation behavior, thereby reducing the number of animals needed for animal trials. However, the zebrafish embryo can not only be used to determine the circulation behavior of nanoparticulate drug delivery systems but also to assess the efficiency of treatment of small molecule drugs. In the field of bacterial infections, emergence of antibiotic resistance

(ABR) is a serious problem. [86] Increasing spread of resistance genes renders conventional antibiotic therapies inefficient. There are several mechanisms by which pathogenic bacteria can counter or evade antibiotic treatment. The most prominent of these mechanisms is the inheritance of antibiotic resistance by either mutagenesis or lateral gene transfer between microorganisms by means of plasmid DNA. [87,88] Another mechanism involves the emergence of dormant forms of bacteria, called persister cells. These non-dividing cells are not per-se resistant to the antibiotic intervention but are almost unsusceptible to such therapies due to their dormancy. [89–92] Furthermore, a number of pathogenic microorganisms including *Salmonella* species are able to survive and replicate within so-called *Salmonella* containing vacuoles (SCV) in macrophages. [93–96] The microorganisms not only evade the innate immune system by this mechanism but also antibiotic treatment, especially in the case of antibiotics that do not cross cell membranes such as tobramycin. A similar strategy is also found in *Mycobacterium* species. [97–99] Consequently, the search for novel antibiotic compounds and antibiotic adjuvants, or novel treatment approaches is a major focus of current research efforts. The applicability of the zebrafish embryo animal model to tackle these problems is discussed in **Chapter 4.1** [100]. Maximizing the effect of already marketed antibiotics using alkylresorcinols as an antibiotic adjuvant (**Chapter 4.2**), [101] and nanoparticle-based delivery of antibiotics directly to macrophages are two possible ways by which the ABR problem can be reduced. The zebrafish embryo animal model could be an interesting model organism to test the two approaches *in vivo* due to the high throughput (alkylresorcinols), and the transparency (macrophage targeting) offered by this animal model.

4 AIM OF THE THESIS

Lipid-based delivery systems are very promising candidates for the delivery of both, nucleic acids, and conventional small drug molecules. However, the mechanisms involved in successful delivery often remain elusive. It was therefore the aim of this PhD thesis to develop optimized gene delivery systems, to investigate mechanisms important for lipid-based drug and gene delivery, and to apply the zebrafish as a proof-of-concept animal model. The following questions were addressed:

- **Evaluation of lipid-based gene delivery vehicles**

What is the influence of the molecular structure of lipids on gene delivery?

What factors are important for successful *in vitro* and *in vivo* gene delivery?

How to simplify lipid synthesis?

- **Evaluation of lipid nanoparticle (LNP)-DNA interactions**

What is the influence of nucleic acid size on LNP-DNA interaction?

Is minicircle DNA superior to parental plasmid DNA?

Does the superiority of minicircle DNA derive from larger numbers of plasmids per nanoparticle?

- **Improvement of lipid nanoparticle-based delivery**

Are viral proteins suitable for targeting purposes?

Is there an alternative to PEG to improve circulation behavior?

- **Novel applications for the zebrafish embryo model**

Can we use the zebrafish as a predictive vertebrate model for antibiotic treatment?

Can macrophage-targeted liposomes improve antibiotic treatment?

5 RESULTS

The present PhD thesis has led to seven publications and is separated into four major working packages (Chapter 1-4):

CHAPTER 1

1.1 Lipid-Based DNA Therapeutics: Hallmarks of Non-Viral Gene Delivery

1.2 Improvement of DNA Vector Delivery of DOTAP Lipoplexes by Short Chain Aminolipids

CHAPTER 2

2.1 Characterization and Optimization of Lipoplexes: How to standardize Assays and avoid Pitfalls

CHAPTER 3

3.1 Optimization-by-design of hepatotropic lipid nanoparticles targeting the sodium-taurocholate cotransporting polypeptide

3.2 Poly(Sarcosine) Surface Modification Imparts Stealth-Like Properties to Liposomes

CHAPTER 4

4.1 Bacteria vs. Antibiotics – Bridging Infection Modeling in *Danio rerio*

4.2 The Use of 4-Hexylresorcinol as Antibiotic Adjuvant

5.1 CHAPTER 1

5.1.1 Chapter 1.1

Lipid-Based DNA Therapeutics: Hallmarks of Non-Viral Gene Delivery

Jonas Buck, Philip Grossen, Pieter R. Cullis, Jörg Huwyler, Dominik Witzigmann

ACS Nano. 2019 Apr 23;13(4):3754–82.

doi: 10.1021/acsnano.8b07858

Highlights: Lipid-based gene delivery systems are among the most promising non-viral gene delivery systems. This review gives a thorough overview over the historic milestones in lipid-based non-viral gene delivery. We summarize factors important for nanoparticle formulation, as well as for *in vitro* and *in vivo* applications. The latest developments in the field of lipid-based gene delivery systems are discussed and an overview over clinical trials involving lipid-based gene delivery is provided.

Lipid-Based DNA Therapeutics: Hallmarks of Non-Viral Gene Delivery

ABSTRACT: Gene therapy is a promising strategy for the treatment of monogenic disorders. Non-viral gene delivery systems including lipid-based DNA therapeutics offer the opportunity to deliver an encoding gene sequence specifically to the target tissue and thus enable the expression of therapeutic proteins in diseased cells. Currently, available gene delivery approaches based on DNA are inefficient and require improvements to achieve clinical utility. In this Review, we discuss state-of-the-art lipid-based DNA delivery systems that have been investigated in a preclinical setting. We emphasize factors influencing the delivery and subsequent gene expression *in vitro*, *ex vivo*, and *in vivo*. In addition, we cover aspects of nanoparticle engineering and optimization for DNA therapeutics. Finally, we highlight achievements of lipid-based DNA therapies in clinical trials.

KEYWORDS: non-viral gene delivery, lipid nanoparticles, DNA, gene therapy, nanomedicine, transfection, nucleic acid delivery, genetic disorders, clinical trials

Inherited genetic diseases represent a considerable public health burden. Gene therapy offers great potential for the treatment of various orphan monogenic disorders.¹ However, the translation from *in vitro* to *in vivo* remains a major hurdle for most nucleic acid delivery systems due to poor *in vitro*–*in vivo* correlation and lack of both efficient and safe carrier systems.² So far, only 4.2% of all clinical trials involving gene therapy approaches reached a late clinical phase.³ The majority of all initiated clinical studies use viral vectors. The low success rate was often attributed to key limitations of viral systems with respect to immunogenicity and generalized toxicity.⁴ Consequently, non-viral lipid-based gene delivery systems have gained much attention due to their reduced immunogenicity, large payloads, safety, and ease of manufacturing.^{5–8} They offer the possibility to transport large biomolecules including nucleic acids with reasonable specificity to diseased target cells.

The term “nucleic acids” here includes various types of nucleic acid polymers such as (but not exclusively) plasmid DNA (pDNA), messenger RNA (mRNA), small interfering RNA (siRNA), or anti-sense oligonucleotides (ASOs). During the last decades, a wide range of nanoparticulate gene delivery systems have been developed. Promising results for RNA interference (RNAi) therapeutics using lipid-based nanoparticles have been achieved and several companies have initiated clinical trials.^{9–11} The first RNAi therapeutic (Onpattro, formerly known as patisiran) to receive FDA approval (August 2018) uses a lipid-

based nanoparticle delivery system.¹² However, these systems do not allow the introduction and subsequent expression of therapeutic proteins. In addition, the induced pharmacological effects obtained by most of these siRNA-based strategies are short-lived, *i.e.*, in the range of days and weeks, in contrast to months, for gene delivery using a DNA expression vector.¹³ Therefore, the use of DNA-based therapeutics offers a favorable option for the induction of long-term therapeutic effects without the need for insertion into the genome and accompanying off-target effects. (The term “DNA therapeutics” is solely used in this Review article as an umbrella term to describe delivery systems for DNA expression vectors. Other DNA therapeutics such as antisense oligonucleotides, aptamers, or DNazymes are not considered.) Theoretically, nanoparticulate gene delivery systems can accommodate large DNA polynucleotides with a size of up to 52.5 kbp (see the [DNA Vector Encoding Gene of Interest](#) section). However, smaller polynucleotides are considered to be more easily encapsulated or more easily translocated to the nucleus (in the case of pDNA). It was shown that plasmids up to a size of 20 kbp can be encapsulated and delivered without hampering the transfection efficiency.¹⁴ Using pDNA expression vectors, it is thus possible to transfer both a gene of interest (“gene delivery” including “knock-in” strategies)

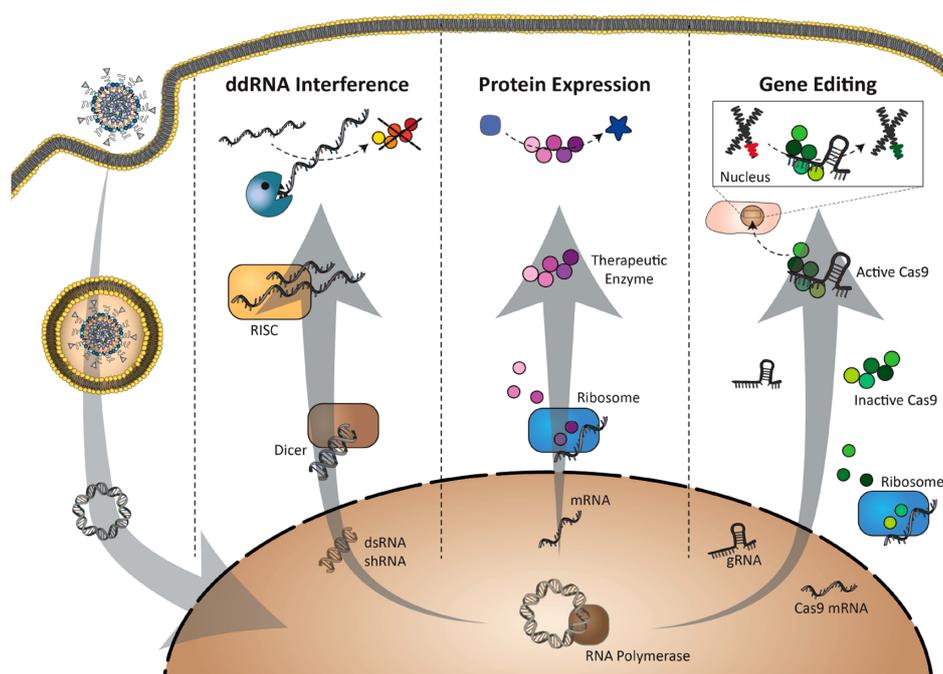

Figure 2. Therapeutic applications for lipid-based DNA therapeutics. (1) DNA-directed RNA interference (ddRNA Interference) can be used to knock down protein expression. The DNA encodes for a shRNA (short hairpin RNA) or dsRNA (double-stranded RNA), which is processed in the cytoplasm by Dicer (an endoribonuclease) to siRNA. Together with argonaute proteins, siRNAs build the RNA interference silencing complex (RISC), which cleaves mRNA of interest and thereby inhibits protein expression. (2) The DNA can also encode for a transgene, which is transcribed into mRNA and translated by ribosomes to a protein of interest such as a therapeutic enzyme. This strategy can be used for enzyme replacement therapy. (3) Gene editing using Zinc finger, TALENs, or CRISPR-Cas technology offers the possibility to genetically modify the host genome and thereby stably express or knock out a protein of interest.

leading to the expression of a functional protein or to “knock-down” target genes by gene silencing using DNA-directed RNA interference (ddRNAi).

For the successful systemic delivery of DNA and subsequent expression of the encoded exogenous protein, many hurdles have to be overcome: (I) efficient nucleic acid packaging, (II) long plasma circulation, (III) extravasation from systemic circulation, (IV) cellular internalization, (V) endosomal escape, (VI) intracellular DNA release, and (VII) nuclear entry.¹⁵ A schematic representation of these hurdles *in vivo* is given in Figure 1.

It is important to note that non-viral gene therapeutics optimized for one type of nucleic acid, *e.g.*, siRNA or mRNA, cannot simply be translated to another type (*i.e.*, DNA vector). This can be due to differences in physical properties such as size or the need for different types of nucleic acids to be delivered to different intracellular sites of action, *i.e.*, cytosol (RNA) versus nucleus (DNA). Kauffman *et al.* have shown significant differences for the translation of siRNA delivery systems to mRNA therapeutics.¹⁶ Kulkarni *et al.* observed that lipid-based formulations optimized for RNA delivery are not optimal for pDNA delivery.¹⁷

In this Review, we discuss recent developments in the field of lipid-based gene delivery systems with a focus on DNA therapeutics. Other therapeutic strategies such as siRNA (RNA knock-down), oligonucleotides (RNA knock-down, translation inhibition, or RNA processing such as splice switch), or mRNA (protein expression), are not covered by this Review

but are summarized in several excellent reviews.^{18–22} We summarize most important key factors for the design of efficient and safe DNA delivery systems. In addition, we address opportunities to develop next-generation DNA therapeutics and discuss their anticipated clinical use.

DNA DELIVERY SYSTEMS

DNA delivery systems can be divided into three different categories: (i) physical methods, (ii) viral delivery systems, and (iii) non-viral delivery systems, which are the topic of this Review. Non-viral DNA delivery systems can be subdivided into another three categories: inorganic materials such as calcium phosphate, lipid or lipid-like materials, and polymeric materials. Although the first reports on gene transfer used calcium phosphate precipitation (see the [Historic Milestones towards Lipid-Based DNA Delivery](#) section), current research in the area of gene delivery mainly focuses on lipid(-like) and polymeric compounds. Advantages and disadvantages of both lipid- and polymer-based gene delivery systems are summarized in Table 1. A detailed comparison of all gene delivery systems including viral vectors and physical methods as well as inorganic materials can be found elsewhere.^{23,24}

LIPID-BASED DNA DELIVERY SYSTEMS

DNA Vectors and Their Mode of Action. The delivery of DNA vectors offers the possibility for three different therapeutic applications: (i) inhibition of protein expression by RNAi, (ii) transient protein production by expression vectors, or (iii) stable

protein expression or knockout by gene editing. These three approaches (Figure 2) can be summarized as follows: ddRNAi is a technology in which DNA vectors encode for short-hairpin RNAs (shRNA), which enable the long-term silencing of specific mRNAs and thus inhibition of protein expression. The intracellular processing in ddRNAi is similar to the endogenous microRNA (miRNA) pathway.²⁵ After the successful delivery of DNA, shRNA is transcribed in the nucleus, processed by the ribonuclease Droscha and exported into the cytoplasm via Exportin 5. In the cytoplasm, Dicer processes the shRNA to siRNA, which is subsequently loaded together with argonaute proteins into the RNA-induced silencing complex (RISC). Depending on sequence complementarity, the RISC cleaves the target mRNA (in case of perfect complementarity between siRNA and mRNA sequence) or represses the translation into the protein (imperfect complementarity). This approach offers an advantage for various diseases because, in contrast to direct siRNA delivery, these effects are long-lasting.

The delivery of DNA vectors in enzyme-replacement or cancer therapy result in long-term transgene expression of an exogenous protein in the target cell. Transgenes encoded on the DNA vector will be transcribed to mRNA and translated into the protein of interest. This protein or enzyme can act intracellularly or extracellularly.

Gene editing or genome engineering is a technique to insert, replace, or delete specific DNA sequences in the genome of host cells. A total of four different nucleases have been used for this strategy: meganucleases, zinc finger nucleases (ZFN), transcription activator-like effector-based nucleases (TALEN), and the clustered regularly interspaced short palindromic repeats (CRISPR)-associated protein (Cas) system. In the case of CRISPR-Cas, a DNA vector can simultaneously encode for the Cas9 protein and a target-sequence specific guide RNA (gRNA). After the transcription of gRNA and translation of Cas9 mRNA, the Cas9/gRNA ribonucleoprotein (RNP) complex will create site-specific double-strand breaks in the genome and insert the transgene by homology directed repair (HDR) mechanisms. Alternatively, a gene can also be silenced or deleted by this technology following nonhomologous end joining (NHEJ).²⁶ Advances in CRISPR-Cas9 technology have been discussed in detail in several recent reviews.^{27–29}

From Research Tool to Therapy. DNA vectors can be applied in a broad range of medical applications ranging from their use as important *in vitro* research tool to *in vivo* applications in patients.

For *in vitro* applications, identifying new drug targets and characterizing the relevance of these targets in early drug discovery are important steps toward development of medicines. In recent years, gene editing techniques such as CRISPR-Cas9 have been used as powerful tools for implementation of such screening and mechanistic studies.³⁰ Furthermore, CRISPR-Cas9 technology can *e.g.*, be used subsequently to generate relevant *in vitro* and *in vivo* disease models.²⁶ Efficient delivery to a wide range of target cells *in vitro* is, however, a prerequisite for these applications. Lipid-based DNA delivery can be a valuable alternative to viral vectors in generating these preclinical models.³⁰ In addition, these systems offer the possibility to co-deliver DNA, RNA (*e.g.*, mRNA or gRNA) and/or proteins to target cells in a coordinated manner.³¹

For *ex vivo* applications, modification of patient-derived cells *ex vivo* has been explored during the recent decade. Major achievements have been made in cancer immunotherapy resulting in the approval of personalized CAR-T cell therapies.

Whereas some technologies were developed to introduce macromolecules to isolated cells without the need for transfection reagents (*e.g.*, microfluidics and electroporation), lipid-based vehicles offer the possibility to efficiently introduce target DNA sequences into patient cells in an *ex vivo* setting to express target proteins or to modify the host cell genome,³² resulting in safe and reproducible transfection.^{33–35}

For *in vivo* applications, whereas *in vitro* or *ex vivo* applications aim for high delivery efficiencies and low toxicity, *in vivo* applications additionally require favorable pharmacokinetic properties and accumulation in target tissues (see the **Factors Important for *in Vivo* Gene Delivery** section). Several candidates have reached clinical development in recent years and a summary of major achievements is provided in the **DNA Therapeutics in Clinical Trials** section.

Historic Milestones toward Lipid-Based DNA Delivery.

The basic process of gene therapy is called transfection and describes the transfer of exogenous genetic material (*e.g.*, DNA) into a cell to exert a therapeutic effect.³⁶ The first attempts toward non-viral gene delivery using chemical reagents were made by Szybalska and Szybalski in the 1960s when they observed an improved “DNA-mediated genetic transformation” in D98 cells upon the addition of spermine to the DNA prior to incubation of the cells.³⁷ However, chemical analysis of spermine revealed that it was contaminated with about 10% calcium. This resulted in calcium phosphate/DNA complexes, which facilitated the delivery of DNA into cells.³⁸ Then, 3 years later, Vaheri and Pagano demonstrated the potential of polymeric substances such as diethylaminoethyl dextran (DEAE dextran) to transfer pDNA to cells.³⁹ In 1973, Graham and Van Der Eb published a detailed study on the effects of calcium phosphate-mediated transfection,⁴⁰ which is generally cited to be the primary source for this transfection technique.⁴¹ A total of 5 years later, Mukherjee *et al.* showed a successful delivery of metaphase chromosomes from hypoxanthine guanine phosphoribosyltransferase (HGPRT) positive cells to HGPRT negative cells using a mixture of unsaturated phosphatidylcholine (PC) and cholesterol 7:2 (w/w) as the transfection reagent.⁴² In 1979, Fraley *et al.* demonstrated delivery of DNA to bacteria using a mixture of PC and phosphatidylglycerol (PG),⁴³ whereas Lurquin showed delivery of DNA to plant cells using either PC or PC/cholesterol, 7:2 (w/w) lipid-based nanoparticles.⁴⁴ A total of 1 year later, again, Fraley *et al.* reported successful delivery of pDNA to African green monkey kidney cells using PC:PG 10:1 (w/w) lipid-based nanoparticles.⁴⁵ The possibility for stable gene transfer using lipid-based nanoparticles was demonstrated by Schaefer-Ridder *et al.* in 1982.⁴⁶ In 1983, Nicolau *et al.* demonstrated successful insulin expression in the liver of rats transfected with intravenously (*i.v.*) injected nanoparticles consisting of a plasmid encoding for rat preproinsulin I and a mixture of PC/phosphatidylserine/cholesterol 8:2:10 (mol/mol) as transfection reagent.⁴⁷

The term lipofection, which describes the transfection of cells using lipid-based transfection reagents, was created in 1987 by Felgner *et al.* when they demonstrated the formation of cationic lipid-based nanoparticles and their use for successful gene transfer and subsequent transgene expression in various cell lines. They synthesized the cationic lipid *N*-[1-(2,3-dioleoyloxy)-propyl]-*N,N,N*-trimethylammonium chloride (DOTMA) and combined it with the helper lipid dioleoylphosphatidylethanolamine (DOPE). After complexation with DNA, they observed fusion of the lipoplexes with the cell membrane of tissue culture

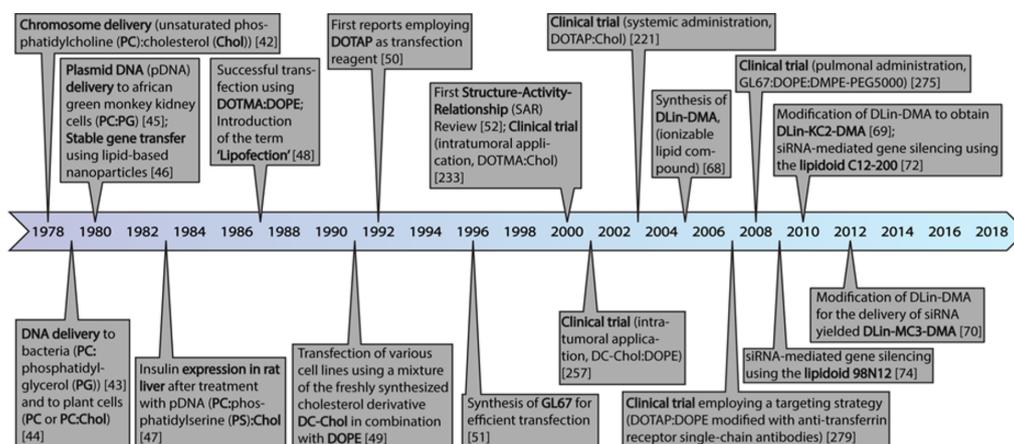

Figure 3. Historic milestones in lipid-based DNA delivery. The timeline displays the historic milestones in lipid-based DNA delivery that are summarized in this review. Each milestone is displayed together with respective references.

Amino Lipids (1st Generation)

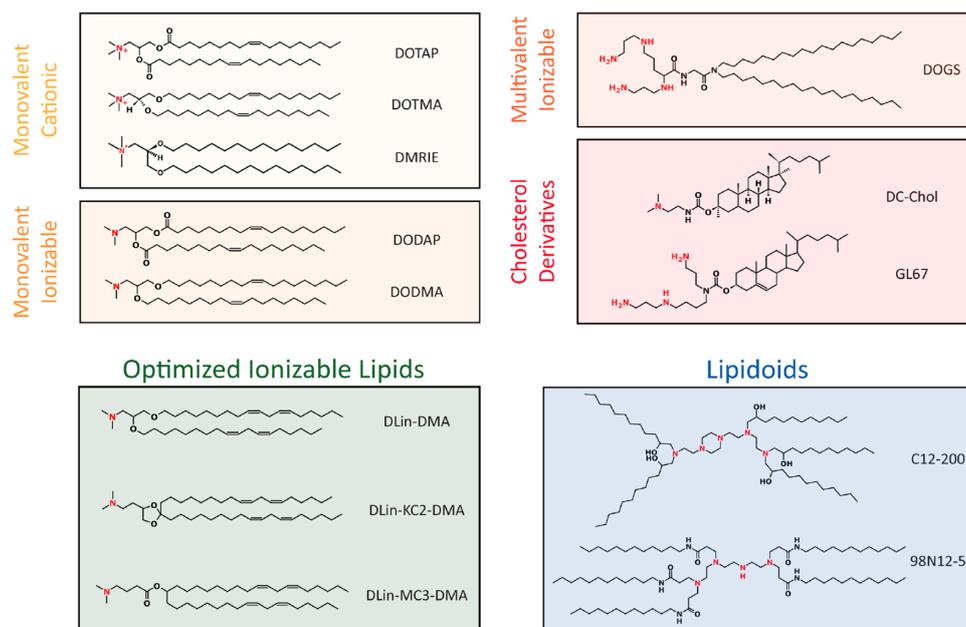

Figure 4. Chemical structures of lipids or lipid-like materials used for the delivery of nucleic acids. Various lipid-based materials have been investigated for the delivery of nucleic acids including RNA and DNA. In general, three different categories have been identified, *i.e.*, first-generation amino lipids, optimized ionizable lipids, and lipidoids. First-generation amino lipids can be grouped into monovalent or multivalent lipids and cholesterol derivatives. All amines with a permanent positive charge (*i.e.*, quaternary amines of monovalent amino lipids) or which are protonated at low pH (such as encounters in the endosomal or lysosomal compartment) are highlighted in red color. A pK_a of around 6.4 is favorable for the endosomal and lysosomal escape of nucleic acids into the cytoplasm.

cells and subsequent diffusion of fluorescent rhodamine-conjugated DOPE throughout the intracellular membranes.⁴⁸ In 1991, Gao and Huang reported successful synthesis of 3 β -[N-(N',N'-dimethylaminoethane) carbamoyl] cholesterol (DC-Chol) and demonstrated efficient transfection of various cell lines using this cationic cholesterol derivative.⁴⁹ A total of 1 year later, one of the first studies employing 1,2-dioleoyl-3-(trimethylammonium) propane (DOTAP) for DNA trans-

fection was published.⁵⁰ Because this study focused on vesicular transport rather than transfection, the technique was used as a tool but was not the focus of the study. In the following decades, many modifications and combinations of these first generation transfection reagents were reported, such as GL67 in 1996,⁵¹ but the basic processes behind gene transfer were poorly understood despite the successful modification of lipids for transfection. The

historic milestones summarized in this section are displayed in Figure 3.

It took until the next millennium until more detailed mechanistic insights were provided (see ref 52). However, the molecular mechanisms of nucleic acid delivery employing cationic lipids are still controversial. DNA often stays at the surface of cells when lipoplexes interact with the plasma membrane.^{53,54} It has been suggested that fusion with the plasma membrane and nanoparticle entry into cells is mediated by the so-called “fusogenic” lipid DOPE.⁵⁵ Consequently, to promote intracellular delivery of DNA, DOPE is included in several commercially available transfection reagents such as Lipofectin (a 1:1 (w/w) mixture of DOTMA and DOPE)⁵⁶ or Lipofectamine (a 3:1 (w/w) mixture of 2,3-dioleoyloxy-*N*-[2-spermine carboxamide] ethyl-*N,N*-dimethyl-1-propanammonium trifluoroacetate (DOSPA) and DOPE).^{57,58}

Key Components of Lipid-Based Gene Delivery Systems. Lipid-based nanoparticles consist of lipids or lipid-like materials to bind DNA, helper lipids to increase transfection efficiency, and a DNA vector encoding for the gene of interest. The chemistry and function of these components are discussed in the following sections.

(Ionizable) Cationic Lipids or Lipid-Like Materials. After initial experiments using phosphatidylserine-based liposomes for DNA delivery,⁴⁵ a vast number of structurally different lipid-based materials have been developed over the last four decades to improve gene-transfer efficiency and safety of resulting lipid nanoparticles.

Three primary categories can be identified, *i.e.*, first generation permanently positively charged amino lipids, optimized ionizable lipids, and lipidoids. All of these share common structural elements such as a hydrophobic moiety that is linked to a hydrophilic headgroup containing cationic or ionizable amine moieties. Examples of the various types of lipid and lipid-like compounds used in gene therapy are discussed in the following sections (Figure 4). Lipids and lipidoids used for RNA delivery have been reviewed recently.^{22,59}

Cationic and Ionizable Amino Lipids (First Generation). In 1987, Felgner and colleagues developed synthetic permanently positively charged cationic lipids for complexation and delivery of DNA.⁴⁸ Even 30 years after their discovery as gene-delivery vehicles, lipids with permanently positively charged headgroups remain the dominant lipid-based gene delivery agents for *in vitro* applications as discussed elsewhere.^{60,61} The positively charged headgroup of cationic lipids can bind and condense the anionic phosphate groups of the DNA backbone *via* electrostatic interactions. The cationic surface charge of such lipoplexes mediates efficient DNA delivery and cellular internalization through interactions with the negatively charged plasma membrane of target cells. Furthermore, positive charges of the lipids in combination with negative charges of anionic lipids in the endosomal membrane promote endosomal escape and, thus, DNA release to the cytosol.⁶²

A large number of cationic headgroup structures have been investigated for lipids used in gene delivery. Headgroups can be categorized in 6 classes: permanently positively charged moieties such as quaternary amines, ionizable amines, amino acids or peptides, guanidiniums, heterocyclic headgroups, and others (*i.e.*, unusual headgroups).⁶³ The ionizable lipids were introduced to achieve systems that exhibited little surface charge at physiological pH, which can lead to severely toxic side effects *in vivo*. Further optimization has led to identification of ionizable lipids with optimized apparent acid dissociation constant (pK_a)

properties that enhance transfection potency (see the **Optimized Ionizable Lipids** section). The hydrophobic tail of cationic lipids for transfection is usually composed of either saturated or unsaturated alkyl chains or steroids. Unsaturated alkyl chains are beneficial with respect to transfection efficiency due to increased lipid membrane fluidity.^{64,65} The first generation of cationic and ionizable lipids can be classified according to their molecular structure as follows (Figure 4):⁶⁶

- (1) monovalent aliphatic lipids characterized by a single positively charged amine moiety in their headgroup such as (a) permanently positively charged cationic lipids, *e.g.*, DOTAP, DOTMA, 1,2-dimyristyloxypropyl-3-dimethylhydroxy ethylammonium bromide (DMRIE) or (b) ionizable cationic lipids that only exist in a positively charged form at pH values below their pK_a , where they are protonated, *e.g.*, 1,2-dioleoyl-3-dimethylammonium propane (DODAP) and 1,2-dioleoyl-3-dimethylammonium propane (DODMA);
- (2) multivalent aliphatic lipids that contain two or more amine functions in their headgroup such as dioctadecylamidoglycylspermine (DOGS); and
- (3) cationic cholesterol derivatives such as DC-Chol and GL67.

Optimized Ionizable Lipids. Whereas cationic lipids can be used to achieve high transfection efficiencies *in vitro*, they are characterized by a relatively high cytotoxicity and unfavorable pharmacokinetic properties *in vivo* (*i.e.*, short half-life in blood circulation and nonspecific binding to cell surfaces). To overcome these limitations, ionizable lipids with optimized pK_a properties have been designed. Ideally, they should (i) be positively charged during lipid nanoparticle formation to allow for nucleic acid complexation, (ii) be neutral at physiological pH for systemic (*e.g.*, intravenous) administration, and (iii) become charged again when accumulating in the endosomal compartment to promote efficient endosomal escape.⁶¹ The first demonstration that an ionizable cationic lipid could be used to encapsulate nucleic acid polymers (*i.e.*, ASO) was made by Semple *et al.*⁶⁷ using DODAP. Subsequently, Heyes *et al.*⁶⁸ developed 1,2-dilinoleoyloxy-3-dimethylaminopropane (DLinDMA) and Semple *et al.*⁶⁹ used a structure–activity relationship (SAR) approach to rationally design lipids with improved gene silencing activity (*i.e.*, siRNA delivery capacity) *in vivo*. The optimized ionizable lipid DLin-KC2-DMA (Figure 4) showed promising results and exceeded the gene silencing capacity of the precursor lipid DLinDMA by a factor of 10.

Further investigations demonstrated a SAR between the pK_a of the ionizable headgroup and the gene silencing efficiency *in vivo*. The most promising compound, DLin-MC3-DMA (Figure 4) with a pK_a of 6.44 was developed⁷⁰ that is now the gold standard for siRNA delivery platforms. In contrast to siRNA, DLin-KC2-DMA-based lipid nanoparticles showed a significantly higher DNA delivery potential as compared to DLin-MC3-DMA-based lipid nanoparticles.¹⁷ This indicates the potential of ionizable DLin-DMA-based lipids for DNA delivery; however, structure–activity relations obtained for RNA do not necessarily apply to DNA delivery.

Lipidoids. Lipid-like materials (*i.e.*, lipidoids) can be synthesized by conjugation of alkyl-acrylates or alkyl-acrylamides to primary or secondary amines.⁷¹ This reaction works in the absence of solvents or catalysts and has, therefore, the advantage that no protection and deprotection steps are needed, which makes this one-pot synthesis straightforward. Akinc *et al.*

synthesized a lipidoid library consisting of 1200 structurally diverse lipid-like compounds.⁷¹ Further modifications of similar lipids and expansion of lipidoid libraries led to the identification of formulations for siRNA-mediated gene silencing *in vivo*, with C12-200 and 98N12-5 as most promising compounds (Figure 4).^{72–74} A structure–function relationship based on four structural and pK_a criteria was established to predict *in vivo* gene silencing efficiency.⁷³ Notably, lipidoids have also been used for *in vitro* pDNA delivery.⁷⁵ Some compounds exceeded the pDNA delivery efficiency of Lipofectamine 2000 by a factor of 4.⁷⁵ Again, compounds optimized for RNA delivery are not necessarily the best for DNA delivery.

Advances in the Development of Lipids for Gene Delivery. Recent advances in the field of gene therapeutics have resulted in several highly potent and biodegradable lipids optimized for mRNA delivery. Sabnis *et al.* synthesized a library of lipids with improved safety profile and enhanced endosomal escape properties.⁷⁶ In addition, several biotechnology companies have initiated screening programs combined with SAR analysis. This has resulted in lipids for mRNA delivery that are orders of magnitude more potent as compared to MC3 (*i.e.*, gold standard for siRNA delivery).⁷⁷ In the future, these advanced lipids need to be tested for DNA vectors to see whether similar benefits are possible.

Lipid Library Screens to Elucidate Structure–Activity–Relationships. Combinatorial synthesis and high-throughput screening (HTS) enable the rapid synthesis and testing of a large number (e.g., hundreds to thousands) of structurally diverse lipid or lipid-like compounds to further unravel structural parameters important for successful nucleic acid delivery. Because RNA-based strategies are currently at the forefront of nucleic acid-based therapeutics, these techniques were mainly applied to materials for RNA delivery rather than DNA. However, both types of nucleic acids share common requirements and findings for RNA can act as a starting point for optimization of DNA therapeutics. Generally, library screens focus on three functional moieties: headgroup–linker–lipid tail.⁷⁸

Headgroup. The cationic (ionizable) headgroup not only is responsible for the interaction with the negatively charged nucleic acids (e.g., nucleic acid condensation) but also affects nanoparticle characteristics such as the surface charge. In this regard, dimethylamino-based headgroups showed superior transfection efficiencies compared to higher substituted moieties.^{69,79,80} Substitution by diethylamino, piperazino, morpholino, or trimethylamino-based headgroups increases steric hindrance as well as the pK_a resulting in decreased activity.^{69,80} In addition, there are reports that indicate headgroups with more than one amine group to be superior.⁷¹ Importantly, several studies demonstrated that a pK_a between 5.5 and 6.5 (optimum of 6.44, but depending on the formulation) is associated with maximal potency *in vivo*.^{33,70,73,81} This ionizable characteristic plays two important roles. First, the headgroup is relatively neutral at physiological pH thereby improving pharmacokinetics (PK) and decreasing toxic effects. Second, the headgroup must exhibit a positive charge in an acidified endosome (pH of ~5–6) to interact with endogenous anionic lipids thereby destabilizing the endosomal membrane to deliver the nucleic acid payload.⁷⁰ Of note, the pK_a is not relevant for permanently positively charged quaternary ammonium-based headgroups.⁸⁰

Linker. The next important functional moiety is the linker that connects the headgroup with its tail group(s). Interestingly, the

linker affects not only the global pK_a of ionizable lipids but also the flexibility for charge presentation or biodegradability of the delivery system. Several groups reported that amide linkers are associated with higher transfection efficiencies *in vitro* as compared to other linkers such as ester or hydroxyl linkers.^{71,75} For ionizable lipids, a gradually decreasing transfection efficiency was reported when alkoxy linkers were replaced for an ester linker. Notably, ester linkers are highly prone to hydrolysis thereby risking to lose activity of the delivery system.⁷⁵ Inclusion of carbamate and thioether linkers resulted as well in poor activity *in vivo*. Only linkers with a ketal function showed increased transfection efficiency when replacing the two alkoxy linkers.⁶⁹ Besides the functional group of the linker, also the spacing between the headgroup and the linker is crucial. A distance between the headgroup functionality and the linker functionality of two carbon atoms promotes the highest efficiency.^{69,81} Further increase or decrease of carbon atoms negatively influences the activity. First, the substitution length of the linker amine can influence the pK_a of amines and thereby alter the global pK_a and subsequent efficiency.⁸¹ Second, the distance between the linker and the headgroup affects the size of the headgroup, which can affect the formation of nonbilayer structures and subsequent destabilization of the endosomal bilayer.⁶⁹

Lipid Tail. The third important functional moiety is the tail group, which generally possesses long hydrophobic carbon chains and is therefore responsible for the “lipid properties”. Lipid tail saturation, length, substitution, and number of tail groups affect the transfection efficiency. Unsaturated tails demonstrated to improve the efficiency of gene delivery systems.⁷⁰ With respect to the tail length, no clear SAR can be summarized. Whereas a tail length in the range of 8–12 carbon atoms demonstrated highest transfection efficiencies in some studies,^{71,73} another library screening showed that increasing the tail length from 14 to 18 carbon atoms increased the transfection efficiency.⁷⁹ The optimal tail length may, therefore, vary among different headgroups or linkers. Tail substitution is another crucial factor. The inclusion of one tail containing a secondary amine is critical for transfection⁷¹ and tails with 3 or more substitution sites, tails containing tertiary and secondary amines, alcohols, branched or linear chains are still effective, while ethers and rings are ineffective.⁷³ Recently, a study demonstrated that branched-tails enhance the potency of lipid nanoparticles due to increased surface ionization at acidic pH (e.g., in endosomes).⁸² Finally, the number of tail groups needs to be considered. Lipid-like molecules that are substituted with only one tail result in poor efficiency compared to their bi-tailed counterparts. However, a synergistic effect could be observed when mixing mono- and bi-tailed lipids at different ratios.^{79,83} Monotailed lipids increase the surface charge, whereas bi-tailed lipids decrease lipid nanoparticle size and increase stability.⁷⁹ In the field of lipidoid synthesis, attachment of more than two alkyl tails is considered to be very important to promote high gene delivery efficiencies.^{71,73}

Additional Lipid Components. As mentioned above, lipid nanoparticles are typically multicomponent formulations. Cationic or ionizable lipid-based materials are often combined with so-called helper lipids. The term “helper lipids” covers a range of charge neutral substances that are included in lipid nanoparticle formulations to improve the performance of the delivery system *e.g.*, by stabilizing the nanoparticle or by improvement of intracellular trafficking.^{84,85} The role of helper

Table 2. Formulation Aspects Influencing Nanoparticle Properties^a

influence factor	effect on	general influence
size of encoding DNA sequence	size of the nanoparticle	plasmid size correlated with lipoplex nanoparticle size when using the cationic lipid RPR120535 no correlation found for Lipopolyamine/DNA nanoparticles
gene delivery system-to-DNA ratio (N/P)	DNA condensation and protection nanoparticle size	high N/P ratios increase DNA condensation within the nanoparticle increasing the N/P ratio decreases nanoparticle size N/P ratios leading to net neutral ζ potential (± 5 mV) promote rapid agglomeration
ionic strength	colloidal stability size	impaired self-assembly and colloidal stability larger nanoparticle size (>150 mM NaCl) smaller nanoparticle size (<20 mM NaCl)
impact of proteins	colloidal stability nanoparticle size	reduced agglomeration of nanoparticles (protein opsonization) reduced nanoparticle size in the presence of serum
complexation volume	transfection efficiency	volumes that are too low may hinder DNA condensation
ζ potential	colloidal stability	highly positive (>+30 mV) or negative (\leftarrow 30 mV) ζ potential hinders nanoparticle agglomeration and therefore improves its stability; neutral ζ potential (± 5 mV) leads to agglomeration

^aA summary of main factors influencing nanoparticle properties (e.g., size and colloidal stability) is provided. The factors are ordered in accordance to the chapters of this Review. Detailed information on the ζ potential is provided in the ζ Potential section of this Review.

lipids in lipid nanoparticles has recently been discussed in detail elsewhere.⁸⁶

Cholesterol is a natural component of biological membranes⁸⁷ and is a major contributor to the cell membrane fluidity, leading to membrane condensation.⁸⁸ Incorporation of cholesterol into lipid-based DNA formulations has been shown to improve stability and transfection efficiency *in vitro*⁸⁹ and *in vivo*.^{90,91} In contrast, replacement of cholesterol with DOPE led to rapid lipoplex dissociation upon contact with serum.⁸⁹ DOPE can induce the non-bilayer inverted hexagonal (H_{II}) lipid phase, which can result in bilayer disruption. This effect is attributed to the small polar headgroup in combination with the two unsaturated oleoyl chains leading to a cone-like shape compatible with the H_{II} phase structure.⁸⁶

Other commonly used helper lipids include phospholipids such as 1,2-dioleoyl-*sn*-glycerol-3-phosphatidylcholine (DOPC), 1,2-distearoyl-*sn*-glycerol-3-phosphocholine (DSPC), or 1-stearoyl-2-oleoyl-*sn*-glycerol-3-phosphocholine (SOPC). Interestingly, Kulkarni *et al.* demonstrated a dramatic increase in reporter gene expression when replacing DSPC with DOPC or SOPC, suggesting that unsaturated lipid chains such as oleoyl chains improve the transfection efficiency compared to saturated lipid chains of the same length.¹⁷ A pair of other studies revealed improved transfection efficiencies when replacing DOPC with DOPE *in vitro*⁸⁵ and *in vivo*,⁸⁴ suggesting an enhanced intracellular trafficking for this type of lipid nanoparticles due to the fusogenic properties of DOPE.

The recognition of DNA therapeutics by immune cells and subsequent clearance from systemic circulation after intravenous administration is a major hurdle for effective therapies. Thus, many lipid-based DNA delivery systems have been modified with a hydrophilic corona to inhibit plasma protein binding and uptake by macrophages. The most common approach to enhance circulation half-life is the concept of PEGylation, *i.e.*, modification of nanoparticles with polyethylene glycol (PEG). These stealth, long-circulating, sterically stabilized systems can be created by incorporation of lipids containing a PEG modification. Notably, neutral and positively charged PEG lipids such as distearoyl-*rac*-glycerol-PEG (PEG-DSG), 1,2-dimyristoyl-*rac*-glycerol-3-methoxy-PEG (PEG-DMG), and PEG-ceramide are superior to PEG lipids with a net negative charge for non-viral gene delivery systems.⁹² Importantly, PEGylation can dramatically reduce transfection efficiency of lipid nanoparticles due to reduced cellular

internalization. This “PEG dilemma” (*i.e.*, improved PK *versus* reduced uptake) has been shown for several nucleic acid delivery systems.^{93–95}

The targeting of cell-specific membrane receptors is a promising strategy to enhance cellular uptake of DNA therapeutics. Targeting can either be achieved by endogenous ligands or synthetic exogenous ligands. For example, lipid nanoparticles containing ionizable lipids can serve as siRNA delivery systems for hepatocyte-specific targeting *via* low-density lipoprotein (LDL) or asialoglycoprotein (ASGP) receptors.⁹⁶ Endogenous mechanisms rely on binding of apolipoprotein E (ApoE) present in the blood circulation to the surface of lipid nanoparticles containing ionizable lipids. This subsequently triggers nanoparticle internalization *via* lipoprotein receptors such as the LDL receptor. Exogenous mechanisms are often based on the modification of lipid-based nanoparticles using a targeting ligand covalently attached to synthetic PEG-lipid. The most advanced strategy for hepatocyte targeting is conjugation of a trivalent *N*-acetylgalactosamine (GalNAc) moiety. This mediates specific binding to the ASGP receptor and subsequent clathrin-mediated internalization.

The concept of active targeting has also been investigated for the delivery of DNA. First clinical trials using single-chain antibody modified nanoparticles to target the transferrin receptor of tumor cells have been initiated (for details, see the **Immuno-lipoplexes** section). In general, many different targeting ligands based on sugars, peptides, proteins, aptamers or antibodies have been investigated, and all of these have different advantages and disadvantages. In addition, various receptors have been evaluated for cell-type specific targeting. Challenges and advances of active targeted nanoparticles have been discussed in detail in several recent reviews.^{5,97}

DNA Vector Encoding Gene of Interest. The efficiency of lipid-based DNA therapeutics is highly dependent on the DNA vector design. Modifications of the DNA vector influence the physicochemical properties of resulting lipid nanoparticles and have direct impact on gene expression efficiency and persistency. As a general rule, a small DNA vector size leads to higher transfection efficiencies. For example, the transfection efficiency of lipid nanoparticles increased by a factor of 6 when the DNA size was reduced from 52 000 to 900 bp.⁹⁸ The use of so-called minicircle DNA (mcDNA), lacking the bacterial backbone (e.g., bacterial origin of replication and antibiotic resistance genes) is, therefore, a promising strategy to improve the therapeutic

Table 3. Formulation Aspects Influencing Transfection Efficiency^a

influence factor	effect on	general influence
size of encoding DNA sequence	duration of transgene expression	prolonged transgene expression using mcDNA
gene delivery system to DNA ratio (N/P)	transfection efficiency	increased transfection efficiency using smaller DNA sequences or mcDNA
	binding to and uptake by cells	increased cell membrane binding and uptake of nanoparticles with increased N/P ratios (unspecific binding also increased)
	DNA condensation and protection	high N/P ratios protect DNA from nucleases due to condensation high N/P ratios might impair DNA dissociation from the nanoparticles after their internalization by cells
	endolysosomal escape	increased endolysosomal escape for higher N/P ratios
complexation pH	transfection efficiency	high N/P ratios lead to increased cytotoxicity
	transfection efficiency	increasing transfection efficiencies up to an optimized N/P ratio
ionic strength	transfection efficiency	increased transfection efficiency at lower pH (DNA condensation is improved)
impact of proteins and cholesterol	binding and uptake by cells	controversial
		reduced binding and uptake if lipoplexes formed in the presence of serum
		accumulation in large intracellular vesicles if lipoplexes formed under serum-free conditions
		accumulation in small intracellular vesicles if lipoplexes formed in the presence of serum
		opsonization promotes macrophage uptake
complexation volume	cell viability	very low or very high serum concentrations detrimental
	endolysosomal escape	endolysosomal membrane destabilization by HSA
	transfection efficiency	reduced transfection efficiency in the presence of serum cholesterol promotes transfection efficiency
		increased transfection efficiency using larger volumes

^aA summary of formulation factors influencing DNA delivery and subsequent transgene expression (e.g., DNA vector design, formulation strategy) is provided. The factors are ordered in accordance to the chapters of this Review.

performance of DNA vectors.⁹⁹ Beneficial effects of mcDNA versus conventional pDNA on the transfection efficiency were demonstrated in several studies.^{100,101} Moreover, mcDNA vectors resulted in long-term transgene expression *in vitro* and *in vivo*.¹⁰¹ Importantly, these effects are not dependent on the type of transfection reagent or cell type and have been described for various targets and application routes *in vivo*.^{100–102} Possible reasons for these findings are an increased diffusion coefficient and an improved nuclear internalization, a more efficient transcription of gene expression cassettes when mcDNA is used, and a higher number of plasmid copies per amount of DNA as compared to large parenteral plasmids.^{100,102–105} Consequently, small DNA vectors (e.g., mcDNA) can be associated with higher transfection efficiencies *in vitro* and *in vivo*. This offers the possibility of reducing the concentration of used transfection reagents to minimize lipid-associated cytotoxicity of these substances.

KEY ASPECTS FOR LIPID-BASED NANOPARTICLE FORMULATION

Besides inherent characteristics of the DNA vector, the formulation (*i.e.*, the mixture of lipid components and DNA vector) is a key factor for efficient non-viral gene transfer. For optimal performance, formulation aspects such as lipid-to-DNA ratio, formulation buffer and production volumes need to be optimized. These factors are summarized and discussed in the following sections. Overviews of formulation aspects influencing nanoparticle properties (Table 2) and gene expression (Table 3) are provided.

Gene Delivery System-to-DNA Ratio. The system-to-DNA (N/P) ratio is defined as the ratio of nitrogen atoms of the lipid headgroup to phosphate atoms of the DNA backbone. At the time point of nanoparticle formation, most of the lipid headgroups must be positively charged to associate with nucleic acid phosphates. The N/P ratio strongly influences the physico- and electrochemical properties of resulting nanoparticles (e.g.,

size, ζ potential, DNA condensation), cellular internalization, endolysosomal escape, cytotoxicity, PK and biodistribution, and, finally, transfection efficiency.

After endocytosis, nanoparticles are trafficked *via* early and late endosomes to lysosomes for degradation. Endosomal membranes contain vacuolar ATPase proton pumps (V-ATPases) and anionic lipids.¹⁰⁶ In the presence of adenosine triphosphate (ATP), V-ATPases shuttle protons and Cl⁻ into these subcellular compartments. Nanoparticles that contain proton-accepting functional groups (e.g., primary, secondary, or tertiary amines) can capture protons and become positively charged. Association of exogenous cationic lipids with endogenous anionic lipids results in membrane disruptive nonlamellar structures that subsequently lead to rupture of the endosomal membrane (shape hypothesis).^{21,107} Thus, high N/P ratios (*i.e.*, high number of exogenous cationic lipids) can enhance this lipid interaction and increase subsequent endolysosomal escape.⁶⁹

Chen *et al.* investigated the N/P-ratio-dependent transfection efficiency of lipid nanoparticles encapsulating siRNA. When the N/P ratio was increased from 1 to 12, the transfection efficiency also increased up to a N/P ratio of 6. Further increase of the N/P ratio yielded only a minor improvement of the transfection efficiency. The authors concluded that a minimum amount of excess cationic (ionizable) lipid is necessary to maximize endolysosomal escape.¹⁰⁸ Similar findings were made for pDNA delivery.¹⁵

In general, low N/P charge ratios lead to poor transgene expression.¹⁰⁹ High N/P ratios lead to increased cytotoxic effects due to noncomplexed cationic lipids that can damage cells.^{110–112} Furthermore, high N/P ratios reduce circulation lifetimes and nonhepatic biodistribution of lipid nanoparticles and can result in toxicity *in vivo*. For example, binding to erythrocytes causes aggregation in lung capillaries and subsequently leads to lung embolism.^{113,114} Interestingly, the N/P ratio inversely correlates with the nanoparticle size of

DOTAP/DOPE, DC-Chol/DOPE, or KC2/helper lipid containing nanoparticles.^{17,115} Similar findings were made with other types of gene-delivery systems.^{116,117} Moreover, a high N/P ratio increases the ζ potential¹¹⁵ and by this increases the homogeneity and stability of lipid nanoparticles due to electrostatic repulsive forces that prevent aggregation.^{117,118} High N/P ratios furthermore protect DNA from degradation by DNase I due to increased DNA condensation.^{15,115} It was shown that fully condensed pDNA is protected against nucleases, e.g., cytosolic nucleases.¹¹⁹ However, very high N/P ratios can impair the dissociation of the DNA after cellular internalization, and therefore, reduce transfection efficiency.^{34,120}

Taken together, these findings indicate that the N/P ratio is closely associated not only with nanoparticle size, ζ potential, and DNA condensation capability but also with toxicity. Increasing N/P charge ratios were found to correlate with decreased cell viability but also with increased transfection efficiency. In general, the transfection efficiency shows a maximum at a certain N/P ratio. There is, however, no optimal N/P ratio that can be used for all types of cationic lipids. Whereas the highest transfection efficiency for cholesterol-derived lipoplexes was found at a N/P ratio of 3:1,³⁴ other types of lipids required much higher N/P ratios.⁴⁸

Formulation Buffer. Complexation pH. In this Review, the complexation pH is defined as the pH at which the lipids and the DNA vector are mixed. The complexation pH can affect the lipid nanoparticle formation depending on the pK_a values of the lipids used. This factor is of special importance when electrostatic interactions between lipids and DNA are the main driver for lipid nanoparticle formation.¹²¹ In general, complexation at lower pH increases DNA binding capacity and resulting transfection efficiency.^{122,123} This is due to higher protonation of the cationic lipids leading to stronger electrostatic interactions with negatively charged phosphate moieties of DNA. For example, higher N/P ratios are needed to obtain lipoplexes with high transfection efficiencies at pH 8 as compared to pH 7 when using the lipids RPR 120535 and RPR 12276.¹²⁴ In the case of optimized ionizable lipids such as KC2 or MC3, DNA is efficiently encapsulated at pH 4, where the lipid is positively charged. Subsequent dialysis of formulated lipid nanoparticles against pH 7.4 results in nanoparticles with low surface charge.

Ionic Strength. The salt concentration during mixing of lipids and DNA can influence the complex formation and the transfection efficiency. High electrolyte concentrations in the complexation medium can shield the charge of cationic lipids and DNA and thus decrease the electrostatically driven self-assembly of lipid nanoparticles.¹²⁴ In addition, the colloidal stability of the solution is reduced.

When lipid nanoparticles with the cationic lipid RPR120535 are prepared at high salt concentrations (150 mM NaCl), the resulting size is larger as compared to formulations prepared at low (20 mM NaCl) salt concentrations.¹²⁴ In general, replacement of saline by glucose in the complexation medium reduces the lipid nanoparticle size.^{116,118} The effect on the resulting transfection efficiency is, however, not conclusive. Whereas for some transfection reagents, high salt concentrations (i.e., up to 600 mM NaCl) increase transfection efficiency,¹²⁵ other reagents show a higher transfection efficiency when produced at low ionic strength (i.e., 10 mM NaCl).¹²³

Impact of Proteins and Cholesterol. Serum is a collective term for a mixture of various plasma protein components (e.g., albumin), inorganic constituents (e.g., bicarbonate), amino acids, nonprotein nitrogen components (e.g., creatine) and their

low-molecular metabolites, carbohydrates, fats and their derivatives, as well as vitamins, hormones, and pigments.¹²⁶ Notably, the composition of serum varies among different species.

It is important to note that serum can strongly influence the performance of DNA delivery systems on different levels: the complex formation and the complex stability as well as the characteristics of cells during *in vitro* experiments. This factor needs to be considered because many cell lines require serum-containing medium for growth and differentiation.

When lipid nanoparticles are formed in serum-containing complexation medium, a reduced binding to plasma membranes, cellular internalization, and transfection efficiency can be observed. In addition, lipid nanoparticles formed in serum containing medium and buffer are often smaller in size.¹⁰⁹ When preformed lipid nanoparticles are diluted, the presence of serum can prevent lipid nanoparticle aggregation due to protein adsorption onto the nanoparticle surface.^{118,127} Lipoplexes formed by cationic lipids RPR 120535 and RPR 121653, for example, show reduced agglomeration in serum-containing medium. However, presence of serum reduces their transfection efficiency *in vitro* by a factor of 100 although the intracellular pDNA concentration is only reduced 2- to 3-fold. The larger lipoplex nanoparticles obtained in serum free conditions were found in large, homogeneous intracellular vesicles, whereas the smaller lipoplex nanoparticles accumulated in small vesicles. Thus, different uptake and intracellular trafficking mechanisms seem to contribute to the difference in transfection efficiencies observed.¹²⁸ Decreased transfection efficiencies upon serum addition during formulation were reported for various lipid nanoparticles. The decrease in transfection efficiency was not significantly affected by the serum type or concentration (e.g., 10% versus 30% fetal bovine serum). Interestingly, complexes containing cholesterol such as DOTAP/cholesterol (DOTAP/Chol) or DOTAP/DOPE/Chol are less sensitive to serum.¹²⁰

Although the exact mechanism is not known yet, it is tempting to speculate that neutral cholesterol reduces the overall electrostatic interactions with negatively charged serum components, thereby reducing the negative influence of serum on the lipid nanoparticle system. In addition, cholesterol increases the packing of phospholipids in lipid bilayers. Dalmen *et al.* showed that high-density lipoproteins (HDL) and LDL trigger release of liposomal drug payload. However, when cholesterol is incorporated into the liposome formulation, the transfer of phospholipids from liposomes to HDL is reduced. As a consequence, the stability of the phospholipid bilayer is increased and drug retention within the liposomes improved.¹²⁹ In addition, a decrease in ζ potential can be observed when positively charged nanoparticles are mixed with serum-containing medium.¹³⁰

Because serum consists of a protein mixture, one needs to consider that not only the extent of protein adsorption but also the types of proteins adsorbed to the nanoparticle surface are critical parameters. *In vivo*, certain serum proteins promote recognition and uptake of nanoparticles by macrophages of the mononuclear phagocytic system (MPS), i.e., opsonins, whereas others such as human serum albumin (HSA) or immunoglobulin A (IgA) can prolong the blood circulation time of nanoparticles (i.e., dysopsonins).^{131,132} Moreover, HSA can promote membrane fusion under acidic conditions and increase endolysosomal escape by facilitating membrane destabilization.¹³³ By pre-incubating nanoparticles prior to incubation or injection, this effect can be exploited to improve the gene delivery efficiency.

Table 4. Factors Influencing Transfection Efficiency *in Vitro*^a

influence factor	effect on	general influence	
nanoparticle size	transfection efficiency	efficiency is increased for pDNA when size is increased efficiency is decreased for siRNA when size is increased	
	cellular uptake	size influences the uptake pathway and speed of uptake but not the amount of internalized NPs expressed as $\mu\text{g NP/cell}$ >1 μm : phagocytosis ≤ 200 nm: clathrin or caveolae-mediated	
	intracellular trafficking	≥ 500 nm: avoidance of lysosomes and endolysosomes smaller NPs are associated with more but smaller NP-containing vesicles in the cytoplasm	
ζ potential	interaction with target cell membranes	positive ζ potentials are associated with stronger interactions with the negatively charged cell membrane	
DNA quantity	toxicity	increased cytotoxicity at higher DNA dosage due to correlating high dose of transfection reagent required	
transfection volume and nanoparticle concentration	transfection efficiency	increased transfection efficiency for increased amounts of DNA	
	nutrient supply	faster nutrient depletion in low transfection volumes	
	toxicity	increased cell viability in larger volumes	
incubation time	transfection efficiency	increased transfection efficiency in lower transfection volumes	
	colloidal stability	agglomeration of lipoplexes over time	
	lipoplex internalization	amount of internalized lipoplexes decreases over time	
	nutrient supply	nutrient depletion during longer incubation times	
	toxicity	increased cell viability after shorter incubation times	
cell lines	transfection efficiency	increased transfection efficiency for longer incubation times	
	cell division rate	higher transfection efficiency in rapidly dividing cells rapidly dividing cells might show a faster nutrient depletion in cell culture media experiments can be conducted in a shorter time when using rapidly dividing cell lines	
	cell surface decoration	differences in cell surface protein expression of various <i>e.g.</i> , receptors allow for targeting	
	endocytic capacity	varies among different cell lines higher endocytic capacities associated with higher transfection efficiency ability for micropinocytosis associated with higher transfection efficiency	
	membrane repair capacity	higher membrane repair capacity for primary cells lower membrane repair capacity for cancer cells and immortalized cell lines	
	secretion pattern	secretion of certain molecules such as pulmonary surfactant may impair transfection efficiency of cationic lipid-based delivery systems	
	transfection efficiency	primary cells harder to transfect immortalized cell lines easier to transfect differences when using different transfection reagents in different cell lines	
	uptake	rate-limiting step in primary cells not rate-limiting step in immortalized cell lines	
	cell density	cell growth behavior	faster cell growth at higher densities (above 50%) slower cell growth at lower densities (below 30%) recovery of exponential growth after passaging is slower when cells grew 100% confluent prior to passaging
	plate coating	toxicity	higher toxicities at lower cell densities due to higher amount of cationic lipid per cell lower toxicities at higher cell densities due to lower amount of cationic lipid per cell
cell viability		increased viability for <i>e.g.</i> , hepatocytes when cultured on collagen-coated culture dishes	
	transfection efficiency	increased transfection efficiency for weakly adherent cells after coating of the culture dish with cationic polymers or ECM proteins	

^aA summary of main factors (in addition to formulation aspects; Table 3) influencing the delivery of DNA and subsequent gene expression *in vitro* is provided. Influence factors are listed in accordance to chapters of this Review.

Simões *et al.* pre-incubated DOTAP/DOPE liposomes with HSA prior to complexation with DNA. HSA coating significantly improved transfection efficiency and transgene expression of lipoplexes. These results were obtained in several cell lines (HeLa, COS-7, the Hut-78 T-cell line derived H9 cell line, B-lymphocytic TF228.1.16 cells, and human peripheral blood monocyte-derived macrophages), as well as *in vivo* in mice. Moreover, HSA coating dramatically reduced the negative effects of serum-containing medium on transfection efficiency. In contrast, non-modified lipoplexes almost completely lost their transfection activity upon contact with serum. The cell viability, however, remained unaffected, suggesting that HSA coating is safe.¹³⁴ Similar studies showed beneficial effects on the toxicity

profile of nanoparticles, most likely due to the shielding of the positive charge by protein adsorption.^{135,136}

Complexation Volume. The complexation volume is defined as the volume in which the lipid components and the DNA are mixed to form the gene delivery system. It should not be confounded with the transfection volume *in vitro*. The complexation volume affects the formation of complexes, and although most formulations are diluted prior to application *in vitro* or *in vivo*, the complexation volume heavily influences the transfection efficiency. High concentrations of DNA, for example, might not allow for a proper condensation and lead to only partially formed nanoparticles or trigger particle aggregation.¹¹¹

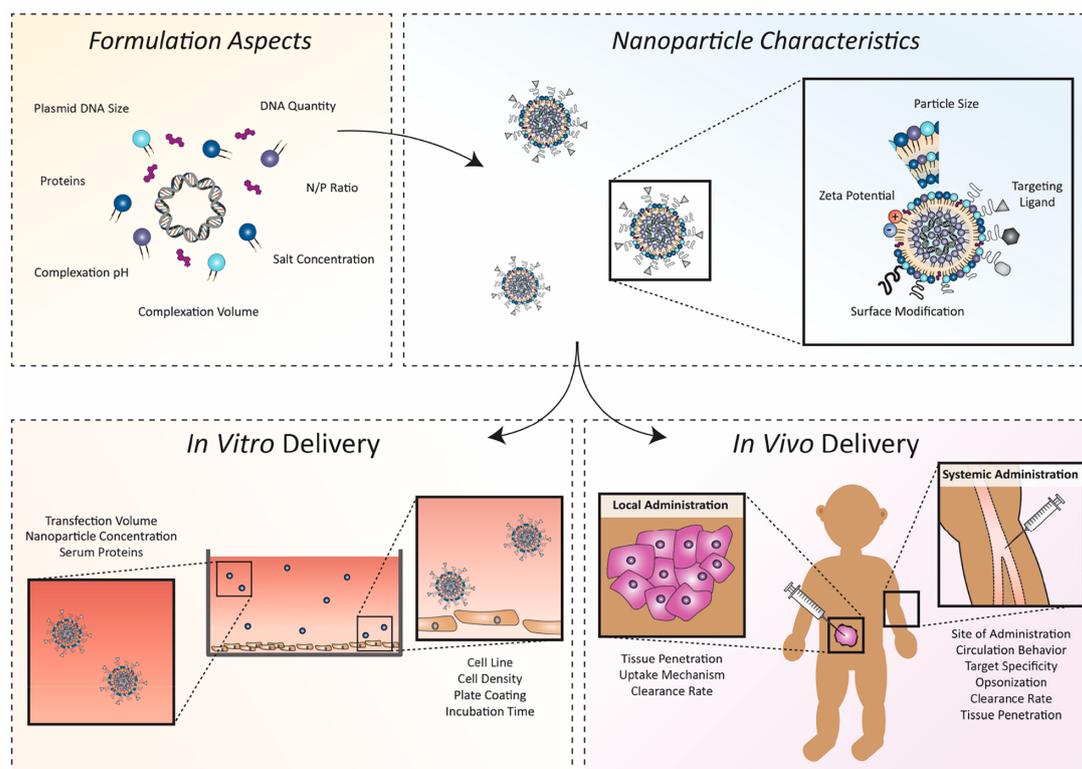

Figure 5. Schematic representation of various factors influencing the gene delivery and gene expression of lipid-based DNA therapeutics. (1) During the formulation process, several aspects have to be considered that influence nanoparticle characteristics and gene delivery efficiency. Complexation pH, volume, salts, and proteins can be influenced using an optimized formulation buffer. DNA characteristics and lipid-to-DNA ratio influence gene expression. (2) Optimized physicochemical properties of lipid-based DNA therapeutics are essential for an efficient gene delivery and need to be adjusted for a cell-type or tissue-specific gene expression. (3) *In vitro*, cell medium and cell characteristics are two important factors influencing gene delivery efficiency. Cell-dependent factors include cell type, cell density (*i.e.*, nanoparticles per cell), cell attachment, and time for nanoparticle uptake. (4) *In vivo* gene delivery is mainly influenced by the route of administration and the nanoparticle PK (*i.e.*, circulation behavior, clearance rate, tissue penetration, targeting capacity, and cellular uptake).

For example, DOTAP/Chol DNA lipoplexes were formed in complexation volumes ranging from 3.2 to 102.2 μL . Although all formulations were diluted to a final volume of 102.2 μL prior to *in vitro* transfection experiments, a significant increase in transfection efficiency was observed when DOTAP/Chol lipoplexes were formed in larger complexation volumes.¹³⁷ However, this effect is dependent on factors such as initial DNA concentration, transfection reagent, and N/P ratio.^{137,138} When DOTAP/Chol lipoplexes are formed at a high N/P ratio, the effect of the complexation volume becomes negligible.¹³⁷

Although higher complexation volumes might be advantageous for certain transfection reagents, the volume for *in vitro* (cell culture dish) and *in vivo* (injection volume) administrations is limited. Protocols such as hydrodynamic injection (8–10% of total body weight) for gene delivery to hepatocytes may be applied in rodents, its application in the clinical setting is, however, limited. The standard protocol for animal experiments involves a normodynamic i.v. injection of a total volume up to 5 mL/kg (1.25% of total body weight).^{139–141}

FACTORS IMPORTANT FOR *IN VITRO* AND *EX VIVO* TRANSFECTION

The efficiency of lipid-based DNA delivery and subsequent gene expression *in vitro* and *ex vivo* is dependent on various factors. In the following sections, we summarize and discuss the influence of nanoparticle design, transfection protocol, and target cell type. An overview of factors influencing the nanoparticle properties, and the transfection efficiency *in vitro* is provided in Table 4 and Figure 5.

Nanoparticle Design. The physicochemical properties (e.g., size and surface charge) of lipid-based DNA delivery systems strongly influence their transfection efficiency *in vitro*. Therefore, optimization of physicochemical characteristics is of crucial importance to enhance DNA delivery and subsequent transgene expression. In the following section, we discuss these key factors, their importance for the design of lipid-based DNA nanoparticles and their influence on gene transfer *in vitro*.

Size. The size of lipid-based DNA nanoparticles is a key characteristic that influences the transfection efficiency *in vitro*. This parameter depends on multiple factors such as the type of cationic or ionizable lipid used,^{110,118,142} N/P ratio,^{115,120} pH of the transfection medium,¹⁴³ preparation method,¹⁴⁴ time frame

for maturation after complex formation,¹⁴² presence of serum,^{109,118,120,127,128,130} or salt concentration during complex formation.^{116,118,124,125} Consequently, nanoparticle size has to be monitored during particle preparation, during storage under different assay conditions, and before use. Despite such precautions, nanoparticle size may increase after addition to cell medium due to binding of plasma proteins and the formation of a biocorona.^{132,143,146}

There is no consensus on whether larger or smaller lipid nanoparticles are more effective (*in vitro*). Some authors hypothesize that large particles sediment *in vitro* onto cultured cells, leading to a higher exposure.^{118,120} In addition, a higher amount of DNA vectors can be incorporated within larger nanoparticles as compared to their smaller counterparts.¹²⁰ Indeed, several research groups reported a positive correlation between nanoparticle size and transfection efficiency in *in vitro* experiments.^{118,120,127} In line with these reports, Almofti *et al.* found that larger lipoplexes resulted in higher transfection efficiencies *in vitro*. Furthermore, lipoplex size was the only nanoparticle characteristic that correlated with transfection efficiency.¹⁰⁹ However, detailed studies revealed that the amount of DNA internalized by cells is independent of nanoparticle size.^{124,147} This finding suggests that not the total amount of delivered DNA is decisive but rather the intracellular processing of nanoparticles and their cargo. Indeed, large intracellular vesicles might be more prone to vesicular disruption than smaller vesicles associated with smaller nanoparticles.^{109,124,128} This might favor endosomal escape and appearance of a higher number of smaller-sized nanoparticles in the cytoplasm.¹⁴⁸

With respect to intracellular trafficking, nanoparticle size heavily influences cellular internalization and intracellular processing.¹⁴⁵ For example, microparticles larger than 1 μm are internalized by antigen presenting cells (APCs) such as macrophages and dendritic cells through phagocytosis, whereas these particles are internalized inefficiently in nonphagocytic cells.¹⁴⁹ Nanoparticles smaller than 200 nm were shown to be rapidly internalized by murine melanoma cells B16-F10 *via* clathrin-mediated endocytosis, whereas larger nanoparticles (*i.e.*, 500 nm) were slowly internalized *via* other pathways. Consequently, smaller nanoparticles accumulated in late endosomes and lysosomes, whereas nanoparticles with a size of 500 nm did not reach the lysosomal compartment.¹⁵⁰

ζ Potential. The ζ potential of a nanoparticle is a measure of the electrokinetic potential between the surface of a tightly bound ion layer (shear plane) and the electroneutral region of the surrounding solution. The ζ potential has practical implications for the colloidal stability of systems containing dispersed particles because this potential, rather than the Nernst potential, governs the degree of repulsion between dispersed particles and the interaction with biological membranes. The ζ potential is mainly influenced by the lipid composition and the N/P ratio. In general, the ζ potential increases with increasing N/P ratio.^{115,151}

On the one hand, it was shown that nanoparticles with a highly positive or negative ζ potential (± 30 mV) have a high colloidal stability due to electrostatic repulsive forces that prevent aggregation.^{120,151} In sharp contrast, nanoparticles with a nearly neutral (± 5 mV) ζ potential rapidly agglomerate.¹⁵² On the other hand, a high positive ζ potential can increase the adsorption of negatively charged plasma proteins to the nanoparticle surface. All of these effects influence nanoparticle size and thus transfection efficiency. Strategies for improved

colloidal stability, such as surface modification with the hydrophilic polymer PEG, were already discussed in the **Additional Lipid Components** section of this Review.

Transfection Protocol. DNA Quantity. The total amount of DNA used during *in vitro* experiments markedly influences the transfection efficiency. As a general rule, higher amounts of DNA result in higher transfection efficiencies. For example, increasing the dose of pDNA per well from 0.5 to 4 μg significantly increased transfection efficiencies in various cell lines when integrin-targeted cationic lipid-based/pDNA nanoparticles were used.¹⁰² Similar findings were made for other types of transfection reagents and cell lines.^{110,153} In transfection experiments with Lipofectamine, lipofectin, cellfectin, and DMRIE-cholesterol, high *in vitro* transfection efficiencies were obtained when pDNA concentrations above 1.33 $\mu\text{g}/\text{mL}$ were used. Lower pDNA concentrations resulted in dramatically decreased transfection efficiencies.¹⁵⁴ It should be noted, however, that very high pDNA doses may also increase cytotoxicity due to the co-administered high doses of cationic lipids. This has been demonstrated by Gao *et al.*, who reported a bell-shaped curve for transfection efficiency *versus* DNA dosage.¹⁴³

Transfection Volume and Nanoparticle Concentration. The transfection volume is defined as the total volume in which cells are incubated with lipid-based nanoparticles for transfection. For practical reasons, the transfection volume is, in most cases, the sum of culture medium and its nutrients accessible for cultured cells during incubation and a constant amount of transfection reagent.

For many lipid-based transfection reagents, low transfection volumes are associated with an increased transfection efficiency due to a higher apparent concentration of DNA nanoparticles. However, not all transfection reagents profit from higher concentrations (*i.e.*, lower transfection volumes). The commercially available lipid-based transfection reagent Lipofectamine 2000 is hardly affected by varying transfection volumes in a certain range while maintaining the same quantity of lipid-based nanoparticles added to cells.¹⁵⁵

In general, decreasing the transfection volume leads to a decreased amount of nutrients and growth factors in cell culture and higher concentrations of transfection reagents. This may result in increased cytotoxicity. Malloggi *et al.* clearly demonstrated that the cell viability increased with increased transfection volumes, irrespective of the transfection agent used.¹⁵⁶ High lipid nanoparticles concentrations can thus reduce transfection efficiency due to reduced cell viability and inefficient transgene expression as also shown for lipid nanoparticles consisting of optimized ionizable lipids.¹⁷ This balance needs to be optimized for each lipid nanoparticle system and experimental setting. A common strategy to reduce toxic effects of high lipid nanoparticle concentrations is to keep the incubation times short and to exchange the cell culture medium.

Incubation Time. The incubation time of cells with lipid nanoparticles strongly influences the transfection efficiency and cytotoxicity. In this Review, the incubation time is referred to as the time frame during which the cells are in contact with the lipid-based DNA complexes (*i.e.*, until medium exchange or assay readout). As a general rule, long incubation times increase the transfection efficiency. However, they may as well lead to cytotoxicity,¹¹⁰ nutrient depletion during the incubation,¹⁵⁴ and aggregation of lipid nanoparticles. In particular, lipoplexes suffer from a rather low colloidal stability. To minimize aggregation of

lipoplexes during transfection, an incubation time frame of 24 h is typically not exceeded.¹¹¹

It was demonstrated that transfection efficiencies of DOTAP or DOTAP/DOPE-based systems reached a maximum after 24–48 h of incubation, whereas shorter or longer incubation times led to reduced transfection efficiencies.¹⁰² DOTAP/pDNA lipoplexes showed a luciferase activity that was 2 orders of magnitude higher 24 h after transfection as compared to 80 h post-transfection.¹⁰² The transfection efficiency of lipofectin/pDNA lipoplexes in MRC5E- and 293E-cells increased when the incubation time increased from 20 min to 4 h.¹⁰² Similar findings were made for other types of transfection reagents.¹⁵⁶ It was demonstrated that longer incubation times are associated with higher amounts of internalized lipid nanoparticles.¹⁵⁷ However, short incubation times reduce the interaction between cells and the DNA/lipid complex and thereby reduce the transfection efficiency.

Target Cells. Cell Lines. In general, cell lines can be separated into primary cells and cultured cells. Primary cells are often more difficult to transfect and the resulting transfection efficiencies are low,¹⁵⁸ whereas immortalized cultured cells such as COS-7, NIH 3T3, HeLa, HEK 293, and CHO often show high transfection efficiencies.

While lipid nanoparticle uptake is rather fast in most cultured cells, membrane binding and cellular internalization seems a rate limiting factor for high transfection efficiencies in primary cells.⁵⁴ Vercauteren *et al.* showed that the slow and inefficient cellular internalization of lipoplexes in primary bovine cells (BRPE) correlated with a low transfection efficiency of these cells, whereas cultured retinal pigment epithelial cell lines (ARPE-19 cells) were efficiently transfected after a rapid lipoplex internalization. Indeed, the low metabolic activity of primary cells (leading to significantly lower cellular growth rates for primary cells as compared to cultured cell lines)¹⁵⁹ results in a low endocytic activity. However, not all cultured cell lines can be transfected efficiently. Differences in the expression pattern of extracellular receptors and intracellular mediators, endocytic activity, and cell division rate can influence the gene delivery efficiency to various cell types. For example, COS-7 cells expressed a luciferase reporter gene 165-fold more efficient as compared to HEK-293 cells using similar DNA delivery conditions. The authors hypothesized that COS-7 cells may have an increased nuclear translocation of inserted DNA due to a markedly increased cell division rate.¹⁴⁸ The synthesis and secretion pattern of various molecules is another cell-line-dependent factor. For example, A549 human lung epithelium carcinoma cells are known to be able to synthesize and secrete saturated PC, an important component of pulmonary surfactant. Secreted lipids can interfere with DNA transfection *in vitro* by disrupting lipid–DNA complexes.^{151,160,161} Replacement of the culture medium prior to transfection may therefore be advisable if epithelial cells are transfected and if the lipid nanoparticles are sensitive to disruption. Similarly, the expression of collagen by cultured and isolated cells can vary between 0.001% and 50% of the total protein content among different cell lines.^{162,163} In addition, differences in endocytic capacity and cell division rate may influence transfection efficiencies *in vitro*. Furthermore, cell lines that express sufficient levels of target receptors should be chosen when actively targeted DNA delivery systems are evaluated. For example, cells that express a high level of the galactose-binding ASGP receptor will show higher transfection efficiencies when nanoparticles are modified with galactose moieties.¹⁶⁴

It should be noted that the extent of many of these phenomena depend on the type of delivery system used. For example, transfection efficiency in C6 rat glioma cells¹²⁷ or caprine and ovine fibroblasts¹⁵⁴ is higher with Lipofectine as compared to DMR1E, whereas the opposite was found in bovine fibroblasts¹⁵⁴ and COS cells.¹⁶⁵ All of these findings highlight the importance to carefully choose a suitable *in vitro* cell model for a specific question to be addressed.

Cell Density. The cell density strongly influences the transfection efficiency and lipid nanoparticle-mediated toxicity *in vitro*. A low cell number results in a high dose of nanoparticles per cell that may result in higher transfection efficiencies.^{110,111} When cells with a confluence of 30%, 60%, and 90% were transfected at a constant lipid nanoparticle concentration, transfection efficiencies of 45%, 27.6%, and 6.5% were achieved.¹⁵⁴ In addition, cells in an exponential growth phase often show a higher protein expression as compared to confluent (resting) cells.¹⁵⁸ However, cytotoxicity may be dramatically increased when a (too-) low cell density is chosen for transfection experiments. This is due to reduced growth rates at low cell densities (e.g., below 50%)¹¹¹ and the increased relative dose of lipid nanoparticles per cell. Consequently, commercially available transfection reagents are often recommended in combination with cells that show a high confluence (e.g., 90–95% for Lipofectamine 2000).

Plate Coating. The type and surface coating of cell culture plates is another factor that influences transfection efficiency. The substrate on which cells are cultured has an impact on, e.g., cell polarity, morphology, proliferation, differentiation, viability, and responsiveness to signaling molecules.¹⁶⁶ In general, cells in suspension are harder to transfect compared to adherent cells.¹⁶⁷ Adherent cultured cells need to attach to a substrate to survive and divide.^{162,168} Whereas positively charged surfaces represents the easiest and most frequently used substrate for culturing strongly adherent cells such as fibroblasts, a pretreatment of the culture plate may be required for other cell types.¹⁶⁹ Typical examples of coating reagents are extracellular matrix (ECM) proteins such as collagen, fibronectin, and laminin^{162,166} or cationic polymers such as poly-L-lysine (PLL), polyornithine,^{170,171} or polyethylenimine (PEI).^{172,173} The coating of wells with cationic polymers or ECM proteins increased the DNA delivery efficiency in weakly adherent HEK-293 and PC-12 cells up to 6-fold. However, no increase in transfection efficiency by coating was observed for strongly adherent primary fibroblasts.¹⁶⁹ Increase in transfection efficiency by plate coating in weakly adherent cells may be a result of decreased detachment of cells (when culture medium is aspirated) and increased cell membrane surface area.¹⁷⁴

FACTORS IMPORTANT FOR *IN VIVO* GENE DELIVERY

***In Vitro* to *In Vivo* Translation.** A major bottleneck in the development of lipid-based DNA therapeutics is the weak correlation between results observed *in vitro* and the actual situation *in vivo*.² Cultured cells are in direct contact with lipid nanoparticles during incubation. However, *in vivo* additional factors such as PK, tissue distribution, safety and tolerability, interactions with the host immune system, and metabolic stability of injected nanoparticles have to be considered. Recently, more than 100 different cationic lipids were investigated for siRNA delivery to hepatocytes *in vitro* and *in vivo*. Surprisingly, physicochemical properties such as ζ potential and the nanoparticle size (when <300 nm) could not be used to directly correlate *in vitro*–*in vivo* transfection efficiencies.¹⁷⁵

Table 5. Factors Important for *in Vivo* Gene Delivery^a

influence factor	effect on	general influence
nanoparticle size	blood circulation time	reduced blood circulation time for smaller NPs
	tissue penetration	enhanced tissue penetration for smaller NPs
	pharmacokinetic behavior	increased NP uptake in spleen and liver for larger NPs
ζ potential	opsonization	increased serum protein opsonization for smaller NPs with higher specific surface area
	interaction with serum proteins	positive ζ potentials favor serum protein opsonization
	pharmacokinetic behavior	positive ζ potentials (>20 mV) as well as negative ζ potentials (\leftarrow 20 mV) may lead to off-target tissue accumulation cationic nanoparticles accumulate in lungs, and anionic nanoparticles are sequestered by liver endothelial cells and spleen
route of administration	pharmacokinetic behavior	accumulation at the site of injection for nanoparticles with poor diffusion capacity
	side effects/toxicity	related to tissue distribution or increased risk after local deposition of cationic lipids

^aSummary of most important factors (in addition to formulation aspects; see Table 3) influencing the lipid-based delivery of DNA and subsequent gene expression *in vivo*. Influence factors are listed in accordance to chapters of this Review.

Classical 2D cell culture models often fail to mimic the *in vivo* situation and fail to predict nanoparticle biodistribution.² However, early screening of hundreds of formulation candidates in preclinical animal models is costly and time-consuming and raises ethical concerns. The limited *in vitro* to *in vivo* translation depicts a key limitation in the development of efficacious lipid-based gene delivery systems. Noteworthy, several recent developments have the potential to bridge this gap by either using non-rodent screening models or by increasing the experimental power of single *in vivo* studies. Increasing number of evidence is highlighting zebrafish (and their embryos) as a model to screen nanoparticle circulation and biodistribution,^{176–179} to analyze nanoparticle toxicity¹⁷⁷ and to assess their therapeutic potential in various disease models.^{180,181} These assays can be performed in high-throughput and the transparency of zebrafish embryos enables whole-body imaging using fluorescence-based techniques.¹⁷⁶ Sieber *et al.* systemically injected liposomal formulations in zebrafish embryos and analyzed the circulation behavior (*i.e.*, PK)¹⁷⁶ and macrophage uptake¹⁷⁸ to optimize lipid composition as well as type and extent of PEGylation.

Other preclinical screening strategies aim to increase the experimental throughput and were optimized for parallel formulation assessment in rodents. The so-called barcoding of nanoparticles using DNA codes allows the injection of hundreds of formulation candidates in the same animal.^{2,182–184} Subsequent decoding by high-throughput techniques such as next generation sequencing (NGS) allows the tracing back of the DNA signal and sequence to a formulation composition. Furthermore, this technique has the main advantage that it can be considered label-free because the drug payload (*e.g.*, pDNA) is directly quantified. This technique allows reducing the number of animals and analytical efforts used for PK and biodistribution by orders of magnitude.

Factors Important for Lipid Nanoparticle Design. An overview of factors important for *in vivo* gene delivery is provided in Table 5 and Figure 5. Several nanoparticle-related characteristics can be optimized to obtain efficient gene delivery *in vivo*. Physicochemical properties such as size and ζ potential need to be considered early in nanoparticle design. Factors such as the route of administration, dosing scheme, or target tissue and cell type are important design restraints. In the following section, these nanoparticle- and therapy-related factors will be discussed in more detail. Because results from *in vitro* cannot be accurately translated to the *in vivo* situation, advanced preclinical

screening tools are of increased interest (see the *In Vitro* to *in Vivo* Translation section).

Size. After administration into the body, lipid nanoparticles need to reach their target tissue. Major hurdles for target tissue accumulation are several tissue and cell specific hurdles, efficient internalization, and release of the nucleic acid payload.¹⁸⁵

Nanoparticles with a hydrodynamic diameter below 6 nm can be excreted *via* renal filtration.^{145,186} Interestingly, nanoparticles consisting of positively charged lipids were shown to be excreted *via* urine even if their size exceeds the glomerular filtration cutoff. For example, lipoplexes that self-assemble *via* electrostatic forces can be destabilized by negatively charged proteoglycans (*e.g.*, heparin sulfate) at the glomerular basement membrane in the kidneys.¹⁸⁷ It was shown that sterically stabilized (*i.e.*, PEGylated) lipid-based nanoparticles with a size of less than 150 nm in diameter are able to accumulate in the bone marrow of rabbits. In contrast, nanoparticles with a size of 250 nm are more efficiently sequestered by the reticuloendothelial system (RES) including spleen and liver-resident macrophages, *i.e.*, Kupffer cells, whereas only a small fraction can be found in the bone marrow.¹⁸⁸

The physiological role of the spleen is the removal of aged or damaged red blood cells and other particles from the blood. Notably, the spleen is endowed with interendothelial cell slits of approximately 200–500 nm, and nanoparticles exceeding this size threshold act as splenotropic agents.^{189,190} Thus, further increase in size (and positive ζ potentials) enhances nanoparticles accumulation in the spleen.¹⁹¹ In addition, increased protein accumulation and opsonization results in enhanced uptake by phagocytic Kupffer cells in the liver.^{132,189,192} These processes finally result in a reduced plasma half-life and decreased gene delivery efficiency to the target cell.

For tissue- or cell-type-specific targeting, nanoparticle size is a key parameter. For example, the fenestrae of human hepatic sinusoidal capillaries have an average diameter of 105 nm with a size range between 50–180 nm.¹⁹³ Notably, these fenestrae parameters might show variations due to pathological conditions.^{194,195} Thus, the delivery of nucleic acids to hepatocytes is unlikely if the diameter of the nanoparticles markedly exceeds that of the fenestrae. Other targets are not (*e.g.*, central nervous system) or not efficiently accessible *via* the central blood circulation (*e.g.*, solid tumors) and require deep tissue penetration. It was shown that smaller nanoparticles and particles with a high aspect ratio exhibit enhanced tissue

Table 6. Lipid-Based DNA Therapeutics in Clinical Trials^a

delivery system	gene	combination therapy	delivery route	indication	phase	status	ClinicalTrials identifier (first received)	ref
DOTAP	FUS1 gene		i.v.	advanced non-small-cell lung cancer (NSCLC)	I	completed	NCT00059605 (2003)	220–224
	FUS1 gene (INGIN-401)	combination with erlotinib	i.v.	stage IV lung cancer (NSCLC)	I/II	recruiting	NCT01455389 (2011)	225–227
	BikDD gene (C-VISA)		i.v.	advanced pancreatic cancer	I	withdrawn	NCT00968604 (2009)	228–232
	CFTR gene	nasal application	nasal application	cystic fibrosis	I	completed		267
DOTMA	interleukin-2 gene	i.t. injections	i.t. injections	squamous cell carcinoma of the head and neck (stage III/IV)	II	completed	NCT00006033 (2004)	233–235
	CFTR gene	nasal application	nasal application	cystic fibrosis	I pilot	completed	NCT00004471 (1999)	237–240
	interleukin-2 gene (Leuvectin)		i.t. injections	prostate cancer	I	completed	NCT00004806 (2000)	
					I/II	Terminated (prostate cancer)	NCT00004050 (2003)	241–245, 268
	HLA-B7 and β 2-microglobulin gene (Allovectin)		i.t. injections	metastatic melanoma head and neck cancer melanoma	II III II	completed completed completed	NCT00044356 (2002) NCT00050388 (2002) NCT00003646 (2004)	246–252
					III	completed	NCT00003647 (2004)	
					pivotal III	completed	NCT00395070 (2006)	
EDMPC	CFTR gene		nasal application	cystic fibrosis	I	completed	NCT00009841 (2001)	253–255
DC-Chol	EGFR Antisense DNA		i.t. weekly for 4 weeks	advanced oral squamous cell carcinoma (head and neck cancer)	I	completed		256–260
	CFTR gene		nasal application	cystic fibrosis	I	completed		269–272
	HLA-A2 gene		injection into nodules administered to the nose and lungs	cervical and ovarian carcinoma	I	completed		261, 262
GL67	CFTR gene		nasal application	cystic fibrosis	I/II	completed	NCT00789867 (2008)	273–275
	CFTR gene		nasal application	cystic fibrosis	IIb	completed	NCT01621867 (2012)	263–266
transferrin-receptor-targeted lipoplexes	PS3 (SGT-S3, scFv transferrin receptor antibody)	docetaxel	systemic i.v. administration	advanced solid tumors	I	completed	NCT00470613 (2007)	276–280
		temozolomide		recurrent glioblastoma	II	recruiting	NCT02340156 (2014)	281
		topotecan and cyclophosphamide		recurrent or refractory solid tumors	I	recruiting	NCT02354547 (2014)	282
		gemcitabine/nab-paclitaxel		metastatic pancreatic cancer	II	recruiting	NCT02340117 (2014)	283
	RB94 (SGT-94, scFv transferrin receptor antibody)		systemic i.v. administration	solid tumors	I	completed	NCT01517464 (2012)	284–286

^aLipid-based nanoparticles for the expression of therapeutic genes are used in several clinical trials. Most approaches are based on passive targeted systems. Recently, transferrin-receptor-targeted lipid-based nanoparticles were evaluated. Different routes of administration were investigated, *i.e.*, intravenous (*i.v.*), intratumoral (*i.t.*), and pulmonary or nasal application. Clinical trials are grouped by delivery system and listed chronologically.

penetration.^{108,186,196,197} Nanoparticle size is therefore a critical design parameter to achieve efficient gene delivery *in vivo*.

ζ Potential. The ζ potential can influence to which extent nanoparticles interact with serum proteins. As a consequence of opsonization, nanoparticles are removed from the bloodstream by phagocytotic cells.¹⁹⁸ For example, Xiao *et al.* demonstrated that micellar nanoparticles with either highly positive or highly negative surface charge are cleared by macrophages following opsonization.¹⁹⁹ Besides influence on macrophage clearance, the ζ potential was also shown to influence the biodistribution of nanoparticles. Cationic nanoparticles interact with negatively charged biological membranes, leading to adsorptive mediated endocytosis and a high systemic plasma clearance *in vivo*. Anionic nanoparticles, however, are at risk to be cleared *via* Stab-2-dependent stabilin scavenger receptors of mammalian liver sinusoidal endothelial cells.¹⁷⁹ Kranz *et al.* demonstrated that a highly positive ζ potential (>20 mV) is associated with predominant nanoparticle accumulation in the lungs, whereas negative ζ potentials (\approx 20 mV) led to almost-exclusive nanoparticle accumulation in the spleen.²⁰⁰ Similarly, Levchenko *et al.* demonstrated an increased liver accumulation of negatively charged lipid-based nanoparticles.²⁰¹ A possibility to overcome difficulties associated with high surface charges is decoration of the nanoparticle surface with PEG.²⁰² However, several issues are associated with PEGylation of DNA therapeutics. First, the use of more than 8 mol % DSPE-PEG2000 for the preparation of PEGylated lipid nanoparticles is associated with an increased risk for liposome destabilization.²⁰³ Second, the PEGylation of nanoparticles may lead to immune responses against PEG, especially in the case of multiple dosing.²⁰⁴ Finally, excessive PEGylation might result in decreased therapeutic efficacy (PEG-dilemma).^{93–95}

Route of Administration. Systemic Administration. Several nanoparticle-related characteristics can result in rapid clearance of nanoparticles from the bloodstream. The lung is the first organ encountered by intravenously injected nanoparticles. Consequently, the *i.v.* injection of (large) cationic nanoparticles or particle agglomerates leads to first-pass filtration in the lung and is likely to provoke severe side effects such as embolism. At later time points, a substantial fraction of cationic nanoparticles can be found in liver or spleen. Cellular uptake is preferentially mediated by endothelial cells (lung) or Kupffer cells (liver).^{205–207} Thus, besides the spatial distribution, a temporal distribution takes place after *i.v.* administration.^{205,208} Several strategies were introduced to overcome these limitations.¹⁹¹

Local Administration. Besides chemical modification of lipids and synthesis of new lipid (-like) materials, local administration is another promising approach to avoid issues related to systemic administration. Lipid-based nanoparticles are invasively deposited within diseased organs or tissues to achieve a (local) therapeutic effect. Due to the focused delivery, the administered dose of the lipid-based DNA therapeutics can be reduced. This strategy is especially favorable for nanoparticles with poor pharmacokinetic properties because the nanoparticles remain at the site of administration.²⁰⁵ Examples of successful local administration of lipid nanoparticles are provided in the following section.

Many solid tumors are characterized by a high interstitial fluid pressure and therefore, systemically administered nanoparticles show a reduced accumulation due to a pressure gradient that limits diffusion.^{209,210} When positively charged GL67/DOPE/1,2-dimyristoyl-sn-glycero-3-phosphoethanolamine conjugated PEG (DMPE-PEG) liposomes were injected intratumorally, a

2000-fold increased expression of a chloramphenicol acetyltransferase (CAT) reporter gene was achieved as compared to systemic administration.²¹¹ In this respect, lipid-to-DNA ratio and total DNA amount are the major influence factors on transgene expression levels, followed by the injection volume and the injection technique.²¹² However, the therapeutic success after intratumoral injection can vary significantly among different tumor models. The optimization of treatment procedures and schemes should thus be performed for every tumor model treated.²⁰⁵ The choice of an adequate preclinical disease (*i.e.*, tumor) model is considered as critical step in the translation of preclinical data to the patient situation.¹⁸⁵ Similar to the intratumoral injection, lipid-based nanoparticles can be administered locally to other tissues such as muscle (intramuscular) and skin (intra-dermal) *via* local injection or to the gastrointestinal tract *via* the oral route.^{213,214} For example, intramuscular injection of lipid nanoparticles coding for viral antigens was able to stimulate a humoral and cellular antiviral immune response (*i.e.*, genetic vaccination).^{215,216} Other strategies aim to locally administer lipid-based nanoparticles to lung or nasal mucosa and local application of lipid nanoparticles was able to improve mucosal immunity.^{205,217} However, the colloidal stability and thus gene delivery efficiency of lipid nanoparticles on epithelial barriers may be impaired due to protective layers of mucus or surfactants.²⁰⁵ Many transfection reagents show a dose-dependent cytotoxicity. Therefore, local side effects may be observed upon local administration. For example, the production of reactive oxygen species was reported upon local lung delivery.²¹⁸

DNA THERAPEUTICS IN CLINICAL TRIALS

In recent years, several lipid-based DNA delivery systems, administered *via* various administration routes, have been investigated in clinical trials mainly focusing on the expression of therapeutic proteins for cancer therapy or treatment of cystic fibrosis (summarized in Table 6). Notably, none of these DNA therapeutics have advanced to a late clinical phase. In the following sections lipid-based DNA therapeutics in clinical trials (registered with ClinicalTrials.gov) are described in detail. Formulation aspects, compositions, and important nanoparticle characteristics are provided.

DOTAP. The first application of DOTAP-based lipoplexes for systemic DNA delivery and subsequent gene expression was published in 1997.²¹⁹ Since then, many preclinical and several clinical tests were performed. In the following section, two DOTAP/Chol-based gene delivery approaches for cancer therapy are described in detail.

FUS1 Gene. *TUSC2/FUS1* is a tumor suppressor gene that mediates apoptosis in cancer cells. However, in many lung cancer patients, FUS1 protein is reduced or lost.²²⁰ The first clinical trial on FUS1 gene delivery using DOTAP/Chol lipoplexes (DC-FUS1) in patients with lung cancer was published in 2012.^{221,222} DC-FUS1 was prepared in two steps, resulting in lipoplexes with a mean particle size around 300 nm.^{223,224} First, cationic liposomes consisting of DOTAP/Chol (20 mM: 18 mM) were formulated using a combination of film rehydration (sterile 5% dextrose), sonication, and sequential extrusion. Second, DOTAP/Chol liposomes were mixed with FUS1 pDNA in equal volumes to a final concentration of 4 mM DOTAP and 0.5 mg/mL pDNA. DC-FUS1 were administered *via i.v.* infusion every 3 weeks at 0.01–0.09 mg/kg (dose escalation). Patients received dexamethasone and diphenhydramine prior to injection to suppress inflammatory responses.²²³

Most common toxicities were hypophosphatemia and fever. Five patients of this platinum-pretreated study cohort achieved a stable disease. Interestingly, transcribed FUS1 mRNA and translated protein were detected in tumor specimen and several genes in the intrinsic pro-apoptosis pathway were changed. In 2011, a phase I/II trial was initiated to investigate the combination of DC-FUS1 nanoparticles with the epidermal growth factor receptor (EGFR) inhibitor Erlotinib.^{225–227}

BikDD Gene. *BikDD* is a potent pro-apoptotic gene with antitumor effect. Xie *et al.* investigated this approach for the treatment of pancreatic cancer.²²⁸ In preclinical animal models, *i.e.*, xenograft and syngeneic orthotopic mouse model, *BikDD* gene delivery using DOTAP:Chol lipoplexes resulted in significant antitumor effects. Gene expression was controlled by the pancreatic-cancer-specific promoter VISA. DOTAP:Chol lipoplexes were produced according to Templeton *et al.* (procedure as described above for DC-FUS1),²¹⁹ *i.e.*, extruded DOTAP/Chol liposomes were mixed with pDNA resulting in complexes between 200 to 450 nm in size. Notably, *BikDD*-based gene therapies showed promising preclinical results in the treatment of various other cancers such as hepatocellular carcinoma, lung cancer, breast cancer, or prostate cancer.^{229–232} However, an initiated phase I clinical trial has been withdrawn prior to enrollment (last updated in May 2015).

DOTMA. DOTMA is the first cationic lipid that resulted in efficient transfection *in vitro*. Consequently, the first clinical trials for the delivery of DNA were based on liposomes consisting of DOTMA combined with cholesterol (equimolar ratio).

Interleukin-2 (IL-2). Interleukin-2 is a potent activator of immune responses. To maximize antitumor response in cancer treatment, the immune-stimulatory effects of IL-2 were investigated.²³³ Cationic DOTMA/Chol liposomes (prepared by microfluidization) were complexed with pDNA encoding for IL-2 at a DNA-to-lipid weight ratio of 1:1 in a solution containing 10% lactose. Resulting lipoplexes were characterized by a mean particle below 200 nm.^{136,234} Patients with squamous cell carcinoma of the head and neck received multiple intratumoral injections.²³⁵ Interestingly, the exogenous pDNA nonspecifically induced interferon (IFN)- γ and IL-12 cytokines. A synergistic effect of IL-2, IFN- γ , and IL-12 within the tumor environment was observed.²³³ Because one patient demonstrated a tumor reduction, phase II clinical studies were initiated. The most-common adverse events were fever and nausea.

DMRIE. In 1993, the potential use of DMRIE for gene therapy applications was demonstrated in combination with DOPE (1:1 molar ratio).²³⁶

CFTR. Because DMRIE/DOPE-DNA lipoplexes resulted in effective transgene expression with minor toxicity in several preclinical studies, the efficacy and safety of lipid-mediated transfer of the cystic fibrosis transmembrane conductance regulator (CFTR) gene by intranasal instillation in patients with cystic fibrosis was evaluated.^{237–240} However, information on physicochemical characteristics of tested lipoplexes and clinical results is scarce. Of note, others reported that DMRIE/DOPE-DNA lipoplexes were characterized by a heterogeneous size distribution with dimensions of at least 100 nm or larger.²³⁹

Interleukin-2. In several preclinical studies, pDNA encoding IL-2 complexed with cationic DMRIE/DOPE-based liposomes (product name: Leuvectin/VCL-1102) showed significant reduction in tumor growth.^{207,241,242} Therefore, this cancer immunotherapy was investigated in several phase I/II studies in patients with metastatic melanoma, renal cell carcinoma (RCC),

and sarcoma. Lipoplexes were prepared immediately prior to injection by vortexing of pDNA with liposomes at a DNA:lipid mass ratio of 5:1 resulting in mean diameters of 200–500 nm.²⁴³ Leuvectin was injected with escalating doses ranging from 0.75 to 4 mg into multiple sites throughout the tumor.^{244,245} In around 75% of all tumors, IL-2 pDNA, IL-2 protein, and infiltrating CD81 were detected. No grade 4 toxicities and only one grade 3 toxicity were observed. Interestingly, two patients with RCC and one with melanoma have achieved partial responses, and around 25% of patients had a stable disease.

Major Histocompatibility Complex (MHC). The delivery of pDNA encoding MHC molecules enables the stimulation of antitumor immune responses. This approach was investigated in patients with metastatic melanoma or hepatic metastasis using DNA encoding HLA-B7 and β 2-macroglobulin complexed with cationic DMRIE/DOPE liposomes (Allovectin-7/VCL-1005).^{246–248} Multilamellar liposomes were prepared by lipid film rehydration using lactated Ringer's solution followed by vortexing. Prior to injection, cationic DMRIE/DOPE liposomes were mixed with pDNA by repeated inversion. Patients received direct injections into tumor lesions with escalating doses up to 250 μ g. In a phase I immunotherapy study of patients with hepatic metastases of colorectal carcinoma, the pDNA (93%), mRNA (33%), and protein (63%) were detected.²⁴⁷ No serious toxicity was observed. In a phase II study of direct intralesional gene transfer in patients with metastatic melanoma, patients received up to 10 μ g of Allovectin-7.²⁴⁸ Only mild to moderate adverse events were observed, and 18% of patients achieved a regression. Several other clinical trials were initiated including a phase III trial with 390 melanoma patients.^{249,250} Unfortunately, the rate of responses was unexpectedly low, and the drug was discontinued.^{251,252}

EDMPC. The first study demonstrating the potential of the cationic lipid EDMPC to deliver DNA to pulmonary cells was published in 1997.²⁵³

CFTR. Due to promising preclinical results, a first-in-human trials in patients with cystic fibrosis was initiated.^{254,255} Liposomes consisting of EDMPC and cholesterol (1:1 molar ratio) were prepared by sonication in 5% dextrose and subsequently mixed with CFTR DNA resulting in lipoplexes above 200 nm. A total of 11 patients received up to 4 mg of DNA using a nasal spray. No adverse events were observed. However, lipoplexes did also not show any activity. No vector-specific mRNA was detected, most probably due to the low efficiency of these lipoplexes in the nasal epithelium.

DC-Chol. The cationic derivative of cholesterol, DC-Chol, was published in 1991 by Xiang Gao and Leaf Huang.⁴⁹ Since then, DC-Chol/DOPE-containing liposomes were investigated for several DNA delivery approaches.

EGFR Inhibition. In squamous cell carcinoma the EGFR is often up-regulated. Therefore, the potential of an EGFR antisense gene therapy was investigated to directly block the production of EGFR in contrast to common inhibitory approaches using monoclonal antibodies. To complex the EGFR antisense DNA, cationic liposomes consisting of DC-Chol and DOPE (produced by microfluidization at a 3:2 molar ratio)²⁵⁶ were mixed with DNA using 1 nmol of liposomes per μ g of DNA.²⁵⁷ Similar studies revealed that final complexes had a relatively large size above 200 nm.^{258,259} In 2009, the results of the first human application were published.²⁶⁰ DC-Chol-based nanoparticles were injected intratumorally at 60 to 1920 μ g of DNA per injection (dose escalation). One-third of the patients

achieved a clinical response, and importantly, no severe toxicities (grades 3 and 4) were observed.

HLA-A2 Gene. The activation of tumor-specific immunity is a promising strategy in the management of various malignant disorders. Therefore, DC-Chol/DOPE lipoplexes containing DNA encoding nonsyngeneic MHC antigens, *i.e.*, the HLA-A2 gene, were investigated in a pair of phase I/II trials.^{261,262} Lipoplexes were prepared by simple mixing of DC-Chol/DOPE cationic liposomes (150–200 nm) and DNA in lactated Ringer's solution. Late-stage cancer patients received four weekly injections into cutaneous nodules with up to 80 μg of DNA. The majority of patients with metastatic cervical or ovarian carcinoma had subsequent local immune responses. However, all patients had progressive malignancies.

GL67. GL-67 is a multivalent cholesterol derivative that was developed for the delivery of pDNA to the lung. Stabilized lipoplexes consisting of GL67, DOPE, DMPE-PEG5000 (1:2:0.05 molar ratio), and pDNA were successfully delivered *via* aerosolization.²⁶³

CFTR. Delivery of DNA encoding the CFTR is a promising strategy for the treatment of cystic fibrosis. Several clinical trials have been initiated investigating different lipid-based delivery systems as discussed elsewhere in great detail.²⁶⁴ Lee *et al.* performed a detailed screening of cationic lipids for efficient gene transfer to airway epithelia.⁵¹ The most-effective lipid was GL67, *i.e.*, 100-fold more active than DC-Chol. After intensive optimization of the formulation, a phase I clinical trial was initiated in 2008 followed by phase II clinical trials by the UK cystic fibrosis consortium (www.cfgenetherapy.org.uk).^{263–266} The incorporation of small amounts of DMPE-PEG5000 enabled the preparation of concentrated lipoplexes with an optimal cationic lipid:pDNA ratio of 0.75:1 for aerosolization. Patients ($n = 78$) received the nebulized lipoplex once per month for 1 year. Lung function was modestly stabilized in some individuals, and no significant adverse effects were observed.²⁶⁶

Immuno-lipoplexes. In recent years, several active targeted gene therapeutics have been developed for the treatment of cancer. To increase specificity and transfection efficiency, active targeting of immunocomplexes to the transferrin receptor is one strategy.²⁷⁶ This strategy was used in clinical trials for the delivery of pDNA encoding for p53 and RB94 *via i.v.* infusion. To deliver the pDNA, cationic immuno-lipoplexes consisting of DOTAP and DOPE were modified with antitransferrin receptor single-chain antibodies (TfRscFv) to target tumor cells more efficiently and trigger internalization. Immuno-lipoplexes were prepared in a three-step procedure.^{277,278} First, liposomes composed of a 1:1 molar ratio of DOTAP and DOPE (including 5 mol % MPB-DOPE for TfRscFv conjugation) were prepared using ethanol injection method. Second, the reduced TfRscFv was conjugated to the cationic liposomes *via* maleimide chemistry. Third, cationic immunoliposomes were mixed with pDNA. The final complexes had a size of around 100 nm in diameter.²⁷⁶

p53. The tumor protein p53 is one of the most important tumor suppressors and is frequently mutated in human cancers. Thus, expression of p53 is an interesting approach to prevent cancer formation and progression. In 2007, the first human clinical trial using liposomal nanoparticles targeted by a single-chain antibody fragment to the transferrin receptor (SGT-53) were used to restore the normal human p53 gene.²⁷⁹ In general, only minimal side effects were observed. Fever and hypotension were the most common low-grade toxicities. A prophylactic regimen including histamine blockade was used. Patients with

different types of cancer were included, and the majority demonstrated a stable disease. Exogenous p53 expression in tumor samples was detected by polymerase chain reaction (PCR) and Western blot analysis. In recent years, several clinical trials have been initiated to combine SGT-53 with standard chemotherapy (*e.g.*, temozolomide, gemcitabine, docetaxel, and topotecan) to achieve tumor regression.^{280,281,283}

RB94. RB94 is a truncated version of the retinoblastoma protein RB110 and functions as a potent tumor suppressor.²⁸⁴ Because human bladder cancers show a high transferrin receptor expression, systemically administered targeted nanoparticles (SGT-94) encapsulating a plasmid encoding RB94 were investigated in preclinical studies.²⁸⁵ The first human clinical trial in patients with genitourinary cancers showed evidence of clinical activity.²⁸⁶ Only minimal side effects were observed. Selective expression of RB94 in metastases was demonstrated by PCR and Western blot analysis.

Lessons Learned from Clinical Trials: Successes, Challenges, and Current Limitations. The aim of all nucleic acid-based non-viral systems is to lead to a clinically useful therapeutic. This has now been demonstrated for a lipid nanoparticle formulation encapsulating siRNA. The approval of Onpatro by the U.S. Food and Drug Administration is a watershed event for non-viral gene therapy approaches. Not only did the drug inhibit further progression of a deadly disease that usually leads to death within 5 years of diagnosis, but also, significant improvements were observed.²⁸⁷ This drug, which contains the optimized ionizable cationic lipid DLin-MC3-DMA and an siRNA to silence a gene called transthyretin (TTR), inhibits the production of TTR in the liver following *i.v.* administration. Mutations in TTR can lead to formation of fibrils that deposit in amyloid plaques in nerve and cardiac tissue, causing progressive neurotoxicity and cardiotoxicity. Onpatro now provides an essentially curative therapy for this monogenic disease. Further, the safety profile of Onpatro is encouraging, with readily managed edema and occasional immunogenic responses on injection that can be managed by slowing injection rates and co-administration of immunosuppressants.²⁸⁸

Onpatro provides validation that clinically effective non-viral nucleic acid therapeutics can be developed. Recent work extending these findings to mRNA for vaccine and gene editing applications suggests this promise extends to most, if not all forms of gene therapy.^{289–291} However, there remain significant challenges. First, the only tissue that is available intravenously is the liver. Lipid-based nanoparticle systems that can deliver nucleic acid therapeutics to immune cells, endothelial cell, tumors, and bone marrow are not yet developed. Second, the differing requirements for small (siRNA) and large (mRNA and pDNA) non-viral formulations are not yet understood, and the molecular mechanisms whereby these systems induce transfection remain obscure. Third, the applicability of these non-viral systems to other tissues available by direct injection have not been characterized. This includes brain, ocular, subcutaneous, and other tissues. Finally, these systems are not yet specific enough. Systems developed for nonhepatic tissues are likely to also be able to transfect hepatocytes, leading to off-target effects, for example.

These issues aside the future is bright for non-viral gene therapies including lipid-based DNA therapeutics. They offer promising approaches to treat most diseases as well as straightforward manufacturing, stability, and other requirements necessary for developing a drug.

Safety Concerns and Adverse Events in Gene Therapy Clinical Trials. Although several clinical studies reported low toxicity after administration of lipid-based DNA therapeutics to humans, substantial clinical adverse responses have been observed.²⁹² Systemic administration of lipid-based DNA therapeutics induced inflammation, hematologic, and serologic changes in a dose-dependent fashion.^{273,293} Therefore, strategies to suppress inflammation and expand the therapeutic window are crucial.²²³ Systemic administration of small molecule inhibitors to suppress nanoparticle-mediated inflammation such as naproxen or dexamethasone have shown clinical significance. To circumvent the co-administration of potent immunosuppressive agents, successful incorporation of hydrophobic dexamethasone prodrugs into lipid-based nanoparticles containing nucleic acids has recently been demonstrated, thereby providing effective immunosuppression.²⁹⁴ Further development will allow the incorporation of such strategies into future clinical trials. In addition, optimization of DNA vectors to reduce inflammatory responses, e.g., by CpG reduction, are necessary.²⁹⁵ This will ultimately also increase the magnitude and duration of transgene expression.

Pharmacokinetic Properties and Physiological Barriers. An important limitation for most lipid-based DNA therapeutics tested in clinical trials are their unfavorable physicochemical nanoparticle properties including high surface charge and large size. After systemic delivery, most cationic complexes predominantly accumulate in the lungs, and large nanoparticles get sequestered by the RES.^{200,219} Taking into consideration that these characteristics impact blood circulation lifetimes, cellular binding, and internalization pathways, future studies need to focus on optimized nanoparticles for delivery to particular tissues. Physiological barriers represent another rate limiting factor for lipid-based DNA therapeutics. For example, in cystic fibrosis patients, DNA therapeutics need to be highly efficient at penetrating the viscoelastic and adhesive mucus layer in the lungs.^{296,297}

Intracellular Barriers. In addition to pharmacokinetic properties, intracellular barriers represent a major hurdle for lipid-based DNA therapeutics impeding their clinical performance. Once internalized into target cells and released into cytoplasm, nuclear trafficking of DNA vectors is fundamental. In contrast to RNA therapeutics, this step represents a potentially rate-limiting barrier for lipid-based DNA therapeutics. The nuclear envelope completely seals the nucleus from the cytoplasm, while the nuclear pore complexes (NPCs) enable the import and export of molecules. Molecules smaller than 50 kDa can freely cross the NPC by passive diffusion, while macromolecules that exceed 50 kDa need to be transported actively across the NPC. Because a double-stranded 20 bp oligomer is reported to have an approximately equivalent size to a 13 kDa polypeptide, pDNA generally exceeds the size limit for passive diffusion into the nucleus and therefore requires active transport mechanisms.²⁹⁸ To increase the likelihood of DNA therapeutics to overcome nuclear barriers, a wide variety of substances including nuclear localization sequences (NLS) were investigated as reviewed elsewhere.^{299,300} In the future, it will be crucial to develop a better understanding of the intracellular trafficking and to design strategies overcoming this bottleneck.

Controlled and Scalable Manufacturing. Manufacturing of lipid-based DNA therapeutics is technically challenging and represents a major challenge for a clinical translation and ultimately commercialization. Cationic complexes tested in clinical trials have mostly been prepared by simple mixing of

cationic liposomes with DNA, which does not guarantee process control and results in batch-to-batch variations. Identification of a robust and scalable manufacturing process to produce monodispersed and size-specific nanoparticles in a reproducible and rapid manner is essential. Microfluidic mixing techniques might represent a controllable process resulting in high entrapment efficiencies and narrow size distributions as shown for siRNA.³⁰¹

CONCLUDING REMARKS

In recent decades, tremendous efforts have been made for the development of non-viral gene therapies. Several lipid-based DNA delivery systems have been developed and excellent results have been achieved in clinical trials for siRNA systems leading to the first approved RNAi therapeutic. Nevertheless, the widespread use of DNA vectors in clinical care is still hampered by low transfection efficiency for certain tissues, imprecise targeting, and unwanted activation of the immune system. Thus, continued research on potent and biocompatible nanomaterials for specific delivery of DNA to target cells and efficient transgene expression is required. The continuous and successful development of next-generation lipids made in the field of RNA therapeutics is an excellent example for the optimization of DNA therapeutics.³⁰² Non-viral gene therapy represents one of the most promising options for the treatment of cancer or monogenic disorders. In the future, this technology can potentially be used for several clinical applications. Examples in the fight against cancer might include ddRNAi and the expression of pro-apoptotic and oncotoxic proteins or tumor suppressors. Patients with orphan monogenic disorders (*i.e.*, rare diseases) would highly benefit from disease-modifying therapeutic options, which replace the mutated enzyme by delivery of their encoding DNA sequences. Finally, the delivery of large nucleic acids can enable the implementation of promising gene editing approaches such as the CRISPR/Cas9 or zinc-finger technology for *in vivo* applications.

Notes

The authors declare the following competing financial interest(s): P.R.C. has financial interests in Acuitas Therapeutics and Precision NanoSystems. The remaining authors declare no conflict of interest.

ACKNOWLEDGMENTS

We thank all collaborators for helpful discussions and apologize to all scientists whose work was not cited in this Review due to space constraints. In addition, we acknowledge the financial support of the “Novartis University Basel Excellence Fellowship for Life Sciences”, “FAG Basel”, and the “Swiss National Science Foundation” (SNF grants No. 174975 and No. 173057). DW and JH have equally contributed as senior scientists to the present work.

GLOSSARY

transfection, introduction of genetic material of foreign origin into cells using biological, chemical, or physical methods to obtain genetically modified (*i.e.*, transgenic) cells; **gene therapy**, treatment of various disorders based on the delivery of nucleic acids to modulate gene expression at DNA or RNA level; **gene silencing**, inhibition of endogenous protein expression based on the delivery of nucleic acid drugs modulating the degradation of mRNA or alternative splicing of pre-mRNA; **gene expression**, expression of therapeutic proteins based on the delivery of nucleic acid drugs encoding the gene of interest; **gene editing**, altering gene expression based on the delivery of nucleic acid drugs encoding nucleases to mediate insertion, deletion, modification, or replacement of DNA sequences in the genome; **ionizable cationic lipids**, lipids containing amine moieties with optimized acid dissociation constant resulting in a net-positive charge at acidic pH (e.g., during formulation or intracellularly) but net-neutral charge at physiological pH (e.g., in circulation)

Improvement of DNA Vector Delivery of DOTAP Lipoplexes by Short Chain Aminolipids

Jonas Buck, Dennis Mueller, Ute Mettal, Miriam Ackermann, Hiu-Man Grisch-
Chan, Beat Thöny, Andreas Zumbuehl, Jörg Huwyler, Dominik Witzigmann

Revised manuscript under review (ACS Omega).

Highlights: Lipid-based gene delivery systems often require sophisticated lipid syntheses including multi-step reactions with low yield. This study shows that short chain aminolipids can be synthesized in a straightforward one-pot approach. The synthesized aminolipids successfully improved DNA vector delivery and cytotoxicity of DOTAP-based lipoplexes. Structure-Activity-Relation demonstrated the superiority of C₁₂ lipid tails and methoxy headgroups over C₁₀ lipid tails and hydroxy headgroups. The pharmacokinetic behavior of DOTAP-based lipoplexes was not altered *in vivo* in the zebrafish embryo animal model after incorporation of aminolipids.

Improvement of DNA Vector Delivery of DOTAP Lipoplexes by Short-Chain Aminolipids

ABSTRACT: Cellular delivery of DNA vectors for the expression of therapeutic proteins is a promising approach to treat monogenic disorders or cancer. Significant efforts in a preclinical and clinical setting have been made to develop potent nonviral gene delivery systems based on lipoplexes composed of permanently cationic lipids. However, transfection efficiency and tolerability of such systems are in most cases not satisfactory. Here, we present a one-pot combinatorial method based on double-reductive amination for the synthesis of short-chain aminolipids. These lipids can be used to maximize the DNA vector delivery when combined with the cationic lipid 1,2-dioleoyl-3-trimethylammonium propane (DOTAP). We incorporated various aminolipids into such lipoplexes to complex minicircle DNA and screened these systems in a human liver-derived cell line (HuH7) for gene expression and cytotoxicity. The lead aminolipid AL-A12 showed twofold enhanced gene delivery and reduced toxicity compared to the native DOTAP:cholesterol lipoplexes. Moreover, AL-A12-containing lipoplexes enabled enhanced transgene expression *in vivo* in the zebrafish embryo model.

INTRODUCTION

Delivery of genetic material to diseased cells is of growing clinical interest. Many inherited liver diseases including Crigler–Najjar syndrome or Gilbert’s syndrome are associated with genetic defects leading to loss of function of proteins or low levels of enzymatic activity.^{1–8} Gene therapy enables the introduction of genetic material (*e.g.*, DNA vectors) encoding for a therapeutic protein, thereby restoring physiological functions. Alternatively, the expression of tumor suppressors, proapoptotic or oncotoxic proteins, offers an interesting option for the treatment of malignant disorders.^{9–16}

In recent years, various nonviral delivery systems have been investigated in preclinical and clinical settings for the delivery of recombinant DNA.¹⁷ Electrostatic interaction of cationic lipids and negatively charged DNA vectors of virtually any size induces condensation. The resulting lipoplexes are formed spontaneously. Their preparation and handling are simple and cost-effective. Moreover, lipoplexes allow for a straightforward transfer “from bench to large-scale production” compared to viral vectors¹⁸ without the risk for insertion of genetic material into the host’s genome as shown for adeno-associated virus vectors.^{19–21} Although cationic lipids overcome some of the limitations described for viral vectors, they encompass some disadvantages: The permanent positive charge of cationic lipids is associated with cytotoxicity,²³ and lipoplex systems generally lack efficiency compared to viral vectors.^{23,24} As a result, only a

few types of cationic lipids have entered clinical trials. In 2017, lipofection (*i.e.*, the introduction of exogenous genetic material by means of lipid-based transfection reagents) accounted for only 4.5% of all clinical trials involving gene therapy.²⁵ As one of the exceptions, 1,2-dioleoyl-3-trimethylammonium propane and cholesterol (DOTAP:chol)-based lipoplexes have been clinically investigated for the treatment of various diseases including lung cancer, breast cancer, prostate cancer, or hepatocellular carcinoma.^{9,13,15,16,26,27} The cationic charge of DOTAP:chol lipoplexes enables facilitated cellular interactions and also accounts for decreased cell viability.^{24,28} Therefore, as observed for many lipoplexes, the use of DOTAP:chol systems is limited by poor transfection efficiency and cytotoxic effects.^{29–32}

The aim of the present study was to maximize the potency of clinically tested DOTAP:chol lipoplexes while reducing toxicity. Based on our finding that short-chain (C_8 – C_{12}) amide lipidoids are potential carriers for siRNA,³³ a combination of short-chain aminolipids and DOTAP:chol-

based lipoplexes was explored to enhance DNA vector delivery. It is noteworthy that enhanced gene silencing and reduced cytotoxic potential were demonstrated for polymeric nanoparticles after combination with natural polyphenols and polyphenol inspired polycatechols.^{34,35} In view of these results, a combinatorial library of different types of aminolipids with chain lengths of C₁₀ or C₁₂ and various headgroups, including aliphatic and heterocyclic functional groups, was synthesized by double-reductive amination. The designed aminolipids were incorporated into DOTAP:chol lipoplexes and screened *in vitro* for transfection efficiency and cellular toxicity. The most promising aminolipid-containing system was then compared to DOTAP:chol lipoplexes for *in vivo* transfection efficiency in the zebrafish embryo model.

MATERIALS AND METHODS

Materials. Text adopted from Neuhaus et al.³⁶ The starting compounds and solvents were purchased from Sigma-Aldrich (St. Louis, MO), Honeywell Fluka (Fisher Scientific AG, Reinach, Switzerland), ABCR (Zug, Switzerland), TCI Deutschland GmbH (Eschborn, Germany), or Acros Organics (Thermo Fisher Scientific, Geel, Belgium) and were used without further purification. For reactions under inert gas conditions, the solvent dichloromethane (DCM) was dried over molecular sieves 4 Å and degassed afterward. Column chromatography was carried out using 230–400 mesh, 60 Å silica gel (Chemie Brunschwig AG, Basel, Switzerland). TLC plates (Merck, Darmstadt, Germany, Silica gel 60 F254) were developed with KMnO₄ solution. ¹H and ¹³C NMR spectra were recorded (as indicated) on Bruker 300, 400, or 600 MHz spectrometer (Bruker, Billerica, MA) and are reported as chemical shifts in ppm relative to TMS, calibrated to the signal of the deuterated NMR solvent (300 and 400 MHz). Spin multiplicities are reported as singlet (s), doublet (d), triplet (t), quintet (qu), with coupling constants (*J*) given in hertz, or multiplet (m). Broad peaks are marked as br. NMR experiments (600 MHz) were performed on a Bruker Avance III NMR spectrometer operating at 600.13 MHz proton frequency. The instrument was equipped with a direct observe 5 mm BBFO smart probe. The experiments were performed at 298 K, and the temperature was calibrated using a methanol standard showing accuracy within ±0.2 K. HRESI-MS was performed on a QSTAR Pulsar (AB Sciex Switzerland GmbH, Baden, Switzerland) spectrometer and are reported as mass-charge ratio *m/z*. IR spectra were recorded on a PerkinElmer Spectrum One Fourier transform infrared (FT-IR) spectrometer (ATR, Golden Gate, PerkinElmer, Basel, Switzerland). 1,2-Dioleoyl-3-trimethylammonium-propane (DOTAP) was obtained from Cordex Pharma Switzerland LLC (Liestal, Switzerland). Glucose was purchased from Roth AG, Switzerland. Dulbecco's modified Eagle's medium (DMEM) high glucose was obtained from Sigma-Aldrich Co. (St. Louis, MO) and supplemented with 10% FCS (BioConcept, Allschwil, Switzerland) and penicillin (100 units/mL)–streptomycin (100 μg/mL) (Sigma-Aldrich Co., St. Louis, MO). Trypsin/EDTA (0.25%) was purchased from Invitrogen, Life Technologies (Zug, Switzerland). FACS buffer, composed of D-PBS (Sigma-Aldrich Co, St. Louis, MO), was supplemented with 2% FCS and 0.1% NaN₃ (Sigma-Aldrich Co., St. Louis, MO). The MTT reagent comprised a 1:10 dilution (v/v) of a 5 mg/mL 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide stock solution in DMEM. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl

tetrazolium bromide was purchased from Carl Roth (Karlsruhe, Germany). SDS was purchased from Bio-Rad Laboratories, Cressier, Switzerland. HCl and isopropanol were obtained from Merck KGaA (Darmstadt, Germany).

The extrusion equipment consisted of 100 nm polycarbonate membranes (Whatman Nuclepore Track-Etched Membranes, GE Healthcare Life Sciences, Buckinghamshire, U.K.), filter supports (Whatman Drain Disc 10 mm PE, GE Healthcare Life Sciences, Buckinghamshire, U.K.), and a hand extruder (Avanti Mini Extruder, Avanti Polar Lipids, Inc., AL). Particle size and ζ-potential measurements were performed using a Delsa Nano C Particle Analyzer (Beckman Coulter, Inc., Indianapolis, IN). Transmission electron microscopy (TEM) was conducted using a CM-100 electron microscope (Philips, Eindhoven, the Netherlands). Transfection experiments and cytotoxicity experiments were conducted in 24-well plates (TPP Tissue Culture Testplate 24, TPP Techno Plastic Products AG, Trasadingen, Switzerland) and in 96-well plates (TPP Tissue Culture Testplate 96F, TPP Techno Plastic Products AG, Trasadingen, Switzerland), respectively. The minicircle DNA was kindly provided by the University Children's Hospital Zürich, Switzerland. Statistical evaluation was carried out using OriginPro 2018 (64-bit) SR1 b9.5.1.195 (Academic) (OriginLab Corporation, Northampton, MA).

Synthesis of Aminolipids. A small library of 12 multitailed aminolipids was obtained *via* reductive amination of decanal or dodecanal with different amines, as depicted in Figure 1. Briefly, the various amines representing the

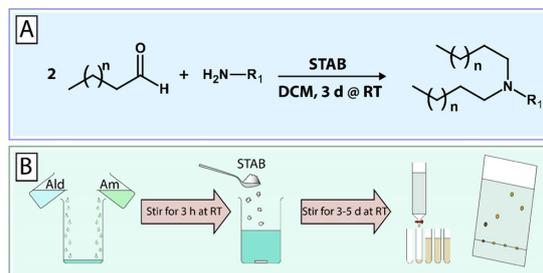

Figure 1. One-pot combinatorial synthesis of short-chain aminolipids *via* double-reductive amination. (A) Double-reductive amination of aldehydes with amines in dichloromethane (DCM) in the presence of sodium triacetoxyborohydride (STAB) as a reducing agent. (B) Briefly, amines (Am) are mixed with excess aldehyde (Ald) and stirred at RT for 3 h followed by the addition of STAB. The reaction continues under stirring at RT for 3–5 days. The obtained aminolipids are then extracted using DCM/brine and then purified by column chromatography (silica, DCM/MeOH 98:2 → 90:10). A detailed description of the chemical synthesis and experimental procedures is provided in the Supporting Information.

headgroups of the respective aminolipids were mixed with excess aldehyde (representing the tails) in dichloromethane (DCM). The mixture was stirred for 3 h at RT, followed by the addition of sodium triacetoxyborohydride (STAB) and further stirred for 2–5 days at RT. Afterward, the solvent was evaporated under reduced pressure. The obtained aminolipids were then redissolved in 30 mL of DCM. Brine (30 mL) was added, and the aminolipids were extracted three times with DCM. The crude product was then purified using column chromatography (silica) and a gradient of an appropriate solvent system, e.g., DCM/MeOH or EtOAc/MeOH (e.g., 98:2

to 90:10 (v/v)). The obtained aminolipid fractions were checked for the presence of aminolipid using thin-layer chromatography (TLC). Clean fractions containing the aminolipid (according to TLC) with the correct mass (determined by MS) were combined, and the solvent was evaporated under reduced pressure. For the final drying step, aminolipid samples were exposed to vacuum using an HV pump for at least 2 days. Detailed descriptions and NMR plots for each aminolipid can be found in the [Supporting Information](#).

Preparation of Aminolipid-Based Systems. DNA Vector Delivery. Aminolipids in chloroform were combined with chloroform stock solutions of cholesterol, DOPE, or DOTAP (1:1 mol/mol) or a combination of either cholesterol and DOTAP, or DOPE and DOTAP (aminolipid:helper:DOTAP = 5:4:1 (mol/mol)) in a glass vial. The (amino-)lipid mixture in chloroform was subsequently dried under nitrogen flow overnight. On the next day, the components were rehydrated using 5% D(+)-glucose solution in Milli-Q ddH₂O to obtain a final DOTAP (or aminolipid-) concentration of 8 mM. Afterward, the mixtures were stirred and vortexed to ensure complete rehydration of the (amino-)lipid components. Following this step, the rehydrated mixtures were subjected to five freeze–thaw cycles (*i.e.*, frozen for 5 min using dry ice followed by thawing for 5 min in a water bath at 62 °C). After freeze–thawing, the (amino-)lipid mixtures were left at room temperature (RT) for 3 h. Subsequently, the mixtures were extruded 15 times through a Whatman Nuclepore Track-Etched Membrane with a pore size of 0.1 μm using an Avanti Mini Extruder.

Physicochemical Characterization of Aminolipid-Based Systems. Directly after extrusion, the size, polydispersity index (PDI), and ζ-potential of the aminolipid nanoparticles were measured using a Delsa Nano C Particle Analyzer at RT, as described previously.^{37,38} Particle size and PDI were determined using CONTIN data conversion after measurement of the extruded nanoparticle preparation (cDOTAP = 8 mM) using a 658 nm laser. Scattered light was detected at an angle of 165°. ζ-Potential data were converted using the Smoluchowski equation after measurement of nanoparticles diluted 1:50 (v/v) in 5% glucose solution at an angle of 15°. Transmission electron microscopy (TEM) images of both pure lipid nanoparticles (LNPs) and LNPs complexed with DNA were acquired on a CM-100 electron microscope (Philips, Eindhoven, the Netherlands). Thus, samples were loaded on a carbon-coated copper grid and counterstained using 2% uranylacetate solution. Excess uranylacetate was removed and the grids were dried at RT overnight prior to TEM imaging.

Cell Culture. HuH7 cells were cultured in high-glucose DMEM, supplemented with 10% fetal calf-serum (FCS), penicillin (100 units/mL), and streptomycin (100 μg/mL) at 37 °C and 5% CO₂. For transfection experiments, the cells were detached at 80–90% confluency using 0.25% trypsin/EDTA (Invitrogen, Life Technologies, Zug, Switzerland) and seeded in 24-well plates (TPP Tissue Culture Testplate 24, TPP Techno Plastic Products AG, Trasadingen, Switzerland) at a seeding density of 5 × 10⁴ cells per well. For cytotoxicity experiments, the cells were detached as for transfection experiments and seeded in 96-well plates (TPP Tissue Culture Testplate 96F, TPP Techno Plastic Products AG, Trasadingen, Switzerland) at a seeding density of 10⁴ cells per well.

Transfection Experiments. DNA Vector Delivery.

Twenty-four hours after seeding, the cells were transfected with minicircle DNA (mcDNA) encoding for enhanced green fluorescent protein (eGFP 1) under the control of a liver-specific p3 promoter. Aminolipid–LNPs were combined with DNA at the indicated ratios and amounts of DNA. Briefly, aminolipid–LNPs and DNA were diluted in separate 1.5 mL Eppendorf tubes in 5% glucose solution. After gentle mixing, the contents of the tubes were combined, and the mixture was left for 30 min on the bench to allow for formation of complexes between aminolipid–LNPs and DNA. After incubation of the DNA with the LNPs, 50 μL of LNP/DNA nanoparticles was added to the cell culture medium (final volume: 1 mL). The ratios of the combination of DNA with LNPs are depicted as the amount of DNA in micrograms and the final concentration of LNPs (μM) in cell culture medium during transfection experiments. The reason for this depiction is that Lipofectamine 3000, whose composition is unknown, was included in the experiment according to the manufacturer's protocol. The amount of Lipofectamine 3000 for transfection experiments was calculated based on an approach relying on the volume of Lipofectamine 3000 in microliters per weight of DNA in micrograms (v/w). This volume per weight approach was maintained throughout the whole study, resulting in a uniform depiction of all samples. Even though no concentration data is available for Lipofectamine 3000, and therefore, it is technically not correct to provide any concentrations for Lipofectamine 3000, we employed an arbitrary concentration for Lipofectamine 3000 assuming that 1 μL of Lipofectamine 3000—as used according to the manufacturer's instructions—is equivalent to 1 μL of DOTAP:chol LNPs. N/P ratios are indicated where applicable.

Transgene Expression Analysis. Confocal Laser Scanning Microscopy. Live-cell images were acquired on an Olympus FV-1000 inverted confocal fluorescence microscope (Olympus Ltd., Tokyo, Japan) 24 and 48 h after transfection to qualitatively assess the transfection efficiency. GFP was excited at 488 nm, and emission was recorded at 516 nm using a UPlanSApo 10× objective (numerical aperture, 0.40).

Flow Cytometry. Transfection efficiency and transgene expression were both measured using an FACS Canto II flow cytometer (Becton Dickinson, San Jose, CA) 48 h after transfection. Briefly, the cells were detached using 0.25% trypsin/EDTA (m/V) for 7 min. Subsequently, trypsin digestion was stopped by the addition of DMEM cell culture medium and the cell suspension was transferred to a 1.5 mL Eppendorf tube. The cell suspension was centrifuged (Eppendorf 5424 R Centrifuge, Eppendorf AG, Hamburg, Germany) at 200g for 5 min at RT. The supernatant was aspirated, the cells were suspended in FACS buffer (D-PBS, 2% FCS, 0.1% NaN₃), and %GFP-positive cells and mean fluorescence intensity (MFI) were measured after excitation at 488 nm. The fluorescence signal of cells expressing GFP was detected in fluorescence channel FL1 (505LP—530/30). Statistical evaluation of the obtained flow cytometry data was done using FlowJo Vx software (TreeStar, Ashland, OR). MFI values were calculated from GFP-positive cells.

Cytotoxicity Experiments. The HuH7 cells were treated with aminolipid–LNPs at various concentrations 24 h after seeding. Four hours after treatment, the medium containing LNPs was aspirated and replaced by a fresh medium. Twenty-four hours after treatment, the medium was aspirated and replaced by a medium containing 0.5 mg/mL 3-(4,5-

dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT). The 96-well plates were then incubated (37 °C, 5% CO₂) for 2 h to allow formation of formazan crystals. Afterward, the medium was aspirated and the insoluble formazan crystals were solubilized using a mixture of 3% SDS in H₂O and 40 mM HCl in isopropanol (1:6, v/v). The plates were then shaken for 2 h, followed by absorption measurement using a 96-well plate reader (SpectraMax M2e Microplate Reader, Molecular Devices LLC, San Jose, CA) at 570 (formazan signal) and 670 nm (background).

Statistical Evaluation. Statistical evaluation was done using OriginPro 2018 (64-bit) SR1 b9.5.1.195 (Academic) Software (OriginLab Corporation, Northampton, MA). A minimum of three independent measurements were used for statistical evaluation.

Zebrafish Embryo In Vivo Trials. Zebrafish culture and injection were carried out as described previously.³⁹ Briefly, zebrafish embryos of the Tg(kdrl:EGFP)⁴⁰ line were raised under standard conditions in accordance with Swiss animal welfare regulations. Fish were maintained at 28 °C in zebrafish culture media supplemented with 1-phenyl-2-thiourea (PTU). Calibrated volumes of 1 nL sample were injected into the Duct of Cuvier (80 pg DNA, 0.64 pmol DOTAP) using a micromanipulator (Wagner Instrumentenbau KG, Schöffengrund, Germany), a pneumatic PicoPump PV830 (WPI, Sarasota, Florida), and a Leica S8APO microscope (Leica, Wetzlar, Germany). Imaging was carried out 4 and 24 h post-injection using a LEICA POINT SCANNING CONFOCAL "SP5-II-MATRIX" (Leica, Wetzlar, Germany) equipped with a 25× HCX IRAPO L (NA 0.95) objective. Image analysis was carried out using Fiji ImageJ v. 1.52n.

RESULTS AND DISCUSSION

Combinatorial Synthesis of Aminolipids. The aim of this study was the design, synthesis, and screening of novel types of short-chain aminolipids to maximize the DNA vector delivery of DOTAP:chol lipoplexes. To create a small lipid library for this proof-of-concept study, we developed a straightforward one-pot combinatorial synthesis based on a double-reductive amination strategy (Figure 1). A combination of various amines and aldehydes in the presence of the reducing agent sodium triacetoxyborohydride (STAB) resulted in the respective short-chain aminolipids with different headgroups and lipid tails.

An overview of selected building blocks as starting materials (*i.e.*, amines and aldehydes) is given in Figure 2A–C. Based on previous findings by our group that short-chain (C₈–C₁₂) lipid-like materials result in improved nucleic acid delivery, decanal (C₁₀) and dodecanal (C₁₂) were selected as building blocks for lipid tails. In addition to aliphatic amines, heterocyclic amines were selected as headgroups based on previous reports that inclusion of aromatic or heterocyclic rings into transfection reagents can increase the transfection efficiency.^{41–45} To test whether these principles also apply to DNA vector delivery based on DOTAP:chol lipoplexes, different building blocks were selected and combined to afford the corresponding aminolipids (see the Supporting Information for synthesis details and aminolipid characterization). For example, aminolipid AL-A10 was synthesized using 3-methoxypropylamine (A) and decanal (C₁₀).

In summary, 12 different short-chain aminolipids were successfully synthesized in high yield using a versatile two-step

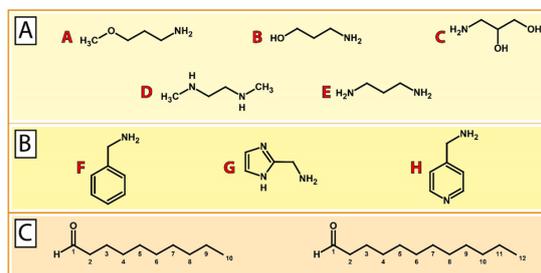

Figure 2. Building blocks for the combinatorial synthesis of aminolipids. (A) Aliphatic amine compounds including (A) 3-methoxypropylamine, (B) 3-aminopropan-1-ol, (C) 3-aminopropane-1,2-diol, (D) *N,N'*-dimethylethylenediamine, and (E) 1,3-diaminopropane. (B) Aromatic and heteroaromatic amine compounds including (F) benzylamine, (G) 1*H*-imidazol-2-ylmethanamine, and (H) 4-(aminomethyl)pyridine. (C) Aldehydes decanal (C₁₀) and dodecanal (C₁₂) as building blocks for lipid tails.

one-pot procedure. This combinatorial synthesis is easy to perform and fully scalable.

Physicochemical Characterization of Aminolipid-Containing Systems. The obtained aminolipids were incorporated into DOTAP-based systems in a 1:1 ratio (mol/mol) using a lipid-film rehydration and extrusion method, as described in the Supporting Information. The results of the physicochemical characterization of aminolipid:DOTAP systems are shown in Figure 3. Most aminolipid:DOTAP systems showed hydrodynamic diameters in the range of 54–79 nm along with a monodisperse size distribution, as indicated by a polydispersity index (PDI) below 0.2 (Figure 3A,B). The largest diameter was measured for the conventional formulation based on DOTAP:chol (108.2 ± 0.6 nm) followed by the AL-H10-containing system (102.0 ± 5.9 nm). The smallest diameter was measured for the AL-C10 system (53.5 ± 2.5 nm) followed by the AL-B10 system (53.8 ± 2.0 nm). Both AL-A10 and AL-A12 systems showed hydrodynamic diameters of 61.5 ± 1.0 and 63.6 ± 0.8 nm and PDI values of 0.185 and 0.181, respectively. Interestingly, incorporation of C₁₀-based aminolipids always resulted in smaller systems compared to their C₁₂ counterparts. All measurements were carried out in triplicate.

The ζ-potential measurements for the obtained DOTAP-based systems revealed a positive surface charge in the range of 18–53 mV (Figure 3C). The highest ζ-potential was found for the formulation including AL-B10 with a highly positive value of 52.27 ± 2.80 mV followed by the AL-A12 system (43.66 ± 1.19 mV). The AL-B12 system showed the lowest ζ-potential with a value of 17.97 ± 4.28 mV followed by the AL-D10 system (21.29 ± 3.48 mV). The AL-A10 system showed a similar ζ-potential to DOTAP:chol (24.86 ± 3.26 vs 28.21 ± 4.31 mV). A highly positive ζ-potential (>30 mV) is indicative of a high colloidal stability resulting from electrostatic repulsive forces that prevent aggregation of particles.^{46,47} Good colloidal stability can still be assumed for systems with ζ-potentials in the range of ±30 mV. This in contrast to a range from 0 to ±5 mV, which is indicative of particle agglomeration and instability.⁴⁸ In fact, during the time course of this study, no precipitation was observed for any formulation. All measurements were carried out in triplicate.

Representative TEM images of DOTAP:chol and the AL-A12-containing system are displayed in Figure 3D,E. Both

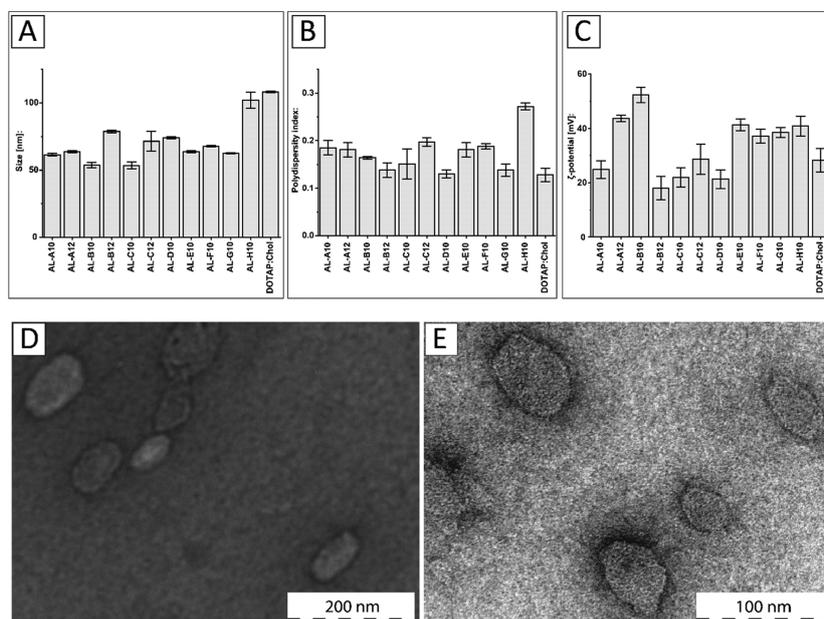

Figure 3. Physicochemical characterization of DOTAP systems combined with short-chain aminolipids. (A) Hydrodynamic diameter (nm), (B) polydispersity index (PDI), and (C) ζ -potential (mV) for aminolipid-containing DOTAP systems compared to the conventional DOTAP:cholesterol (chol) system at a 1:1 ratio (mol/mol). (D) Transmission electron microscopy (TEM) of DOTAP:chol and (E) AL-A12-containing systems.

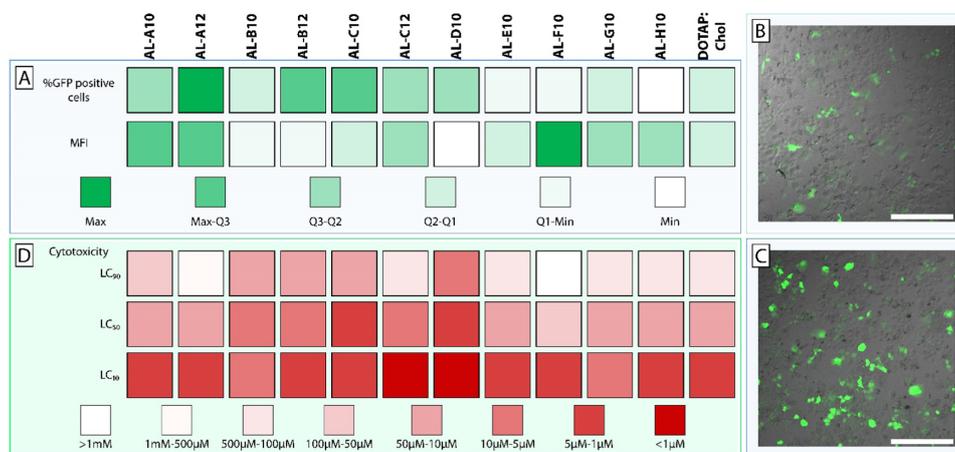

Figure 4. *In vitro* assessment of transfection efficiency and cytotoxicity of lipoplex systems. (A) Heat map representing the transfection efficiency of aminolipid-containing DOTAP lipoplexes compared to conventional DOTAP:cholesterol (chol) composed lipoplexes. Transfection efficiency was assessed by means of percentage of GFP-positive cells and mean fluorescence intensity (MFI) of GFP expression using flow cytometry. The obtained results were allocated to different groups (color code) based on the quartiles of %GFP-positive cells and MFI. Representative confocal images of HuH7 cells transfected with (B) DOTAP:chol or (C) AL-A12-containing lipoplexes entrapping minicircle DNA coding for GFP (scale bar = 400 μ m). (D) Cytotoxicity of aminolipid-containing DOTAP lipoplexes compared to conventional DOTAP:chol lipoplexes by means of lethal concentrations (LC 10/50/90) resulting in 90/50/10% cell viability, respectively.

systems resulted in spherical assemblies with diameters of 82.81 ± 24.64 nm (DOTAP:chol) and 46.13 ± 8.85 nm (AL-A12 containing system), which is slightly smaller than the diameters based on dynamic light scattering (DLS). In conclusion, short-chain aminolipids can be successfully incorporated into DOTAP-based systems, thereby influencing the size and charge of the resulting particles.

Assessment of DNA Vector Delivery *In Vitro*. To assess the efficiency of DNA delivery, we selected an advanced DNA vector type, *i.e.*, minicircle DNA, which has clear advantages over plasmid DNA. Several research groups have demonstrated that the use of minicircle DNA results in high transfection efficiencies and long-lasting transgene expression.^{49–51} Therefore, a minicircle DNA encoding the reporter gene for green

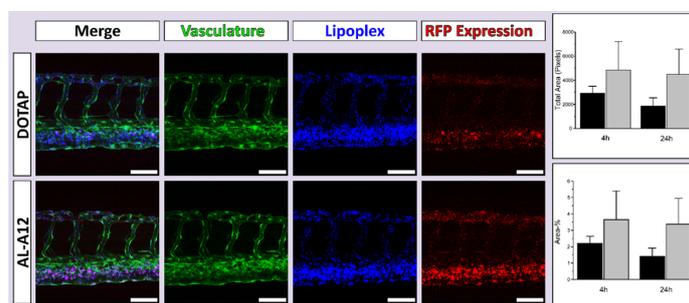

Figure 5. Assessment of *in vivo* transfection efficiency of the lead lipoplex system containing aminolipid AL-A12. Evaluation of lipoplex biodistribution and transfection efficiency *in vivo* in the zebrafish model. Confocal imaging (maximum intensity projections) of transgenic zebrafish embryos with GFP expressing vasculature endothelial cells was performed 4 and 24 h post-injection with fluorescent DOTAP:chol or AL-A12-based lipoplexes entrapping plasmid DNA encoding for RFP. Representative maximum intensity projections of a series of three images are shown (4 h post-injection). Displayed are the merged images, the vasculature expressing GFP (green), the DiI-labeled lipoplexes (blue), and the reporter gene expression (RFP, red). AL-A12 promoted a qualitatively higher gene expression than DOTAP:chol-based lipoplexes. Scale bars = 80 μm . The right graphs show the quantitative image analysis using Fiji ImageJ of the total area in pixels (top) and the percentage of the area (bottom) of the RFP expression determined 4 and 24 h post-injection of DOTAP:chol (black) and AL-A12-based lipoplexes (gray). The results were not statistically significant at $p < 0.05$.

fluorescent protein (GFP) was complexed using DOTAP:chol and aminolipid-containing systems. The lipoplexes were not PEGylated to reduce complexity, thereby allowing us to attribute observed effects directly to the formulation components. Resulting lipoplexes were used for transfection of human liver-derived HuH7 cells *in vitro* (Table S1). A color-coded summary of the transfection screening is shown in Figure 4A. DOTAP:chol lipoplexes (at 1 μg DNA and 8 μM lipid concentration) resulted in 5.7% GFP-positive cells. Compared to the conventional DOTAP:chol system, incorporation of various aminolipids based on aliphatic amines resulted in improved transfection efficiencies (*i.e.*, AL-A to AL-D). For example, AL-B12 and AL-C12 systems resulted in 8.6 and 6.0% GFP-positive cells, respectively. The lipoplexes containing AL-A10 (7.7%) and AL-A12 (10.3%) showed a significantly increased transfection efficiency compared to DOTAP:chol ($p < 0.001$), which was even more distinct at 2 μg DNA and 16 μM lipid concentration with 28.7% (AL-A10) and 31.5% (AL-A12) compared to 13.2% (DOTAP:chol). Moreover, AL-A12 showed 72% of the transfection efficiency of Lipofectamine 3000 (47.5% GFP-positive cells). In contrast, DOTAP:chol was only 30% as efficient as Lipofectamine 3000. A statistically significant ($p < 0.001$) increase in transgene expression (*i.e.*, assessed based on mean fluorescence intensity (MFI)) compared to DOTAP:chol was only observed for AL-A12. While DOTAP:chol only resulted in 10% of the gene expression achieved with Lipofectamine 3000, AL-A12-based lipoplexes exhibited 20% of the transgene expression of Lipofectamine 3000. The replacement of aliphatic amine headgroups with heterocyclic groups (*i.e.*, AL-F10, AL-G10, and AL-H10) to improve the fusogenic properties (as previously described⁵²) did not maximize the efficacy (*i.e.*, % GFP-positive cells) of DOTAP-based lipoplexes (Figure 4A). However, AL-F10 (at 1 μg DNA and 8 μM lipid concentration) resulted in the highest transgene expression among all aminolipids of the combinatorial library. It is tempting to speculate that AL-F10 enhanced the endosomal escape in transfected cells, resulting in increased GFP expression. Due to the small number of investigated heterocyclic headgroups, further studies are warranted to

clarify if such a strategy is applicable for DOTAP-based lipoplexes.

To further improve the understanding of how the aminolipids' structural parameters influence the transfection efficiency, specific compounds were selected for a structure–activity relationship (SAR) study (Figure S37). Aminolipids consisting of a bifunctional methoxy headgroup (AL-A10, AL-A12) showed significantly ($p < 0.001$) higher transfection efficiencies and transgene expression levels compared to aminolipids with a bifunctional hydroxy headgroup (AL-B10, AL-B12). SAR analysis of tail groups revealed significantly higher transfection efficiencies ($p < 0.1$) and transgene expression levels ($p < 0.001$) for aminolipids consisting of C₁₂ tails compared to aminolipids consisting of C₁₀ tails, as demonstrated by the superiority of AL-A12 over AL-A10. Due to the poor transfection efficiency of many of the tested aminolipids, an in-depth SAR analysis focusing on headgroups could not be performed. Further experiments with an expanded range of aminolipid tail lengths and alternative headgroups are needed to improve our understanding on how small changes in lipid tail length influence the delivery of DNA vectors.

In conclusion, the highest transfection efficiency was achieved using AL-A12 lipoplexes with a 2-fold increased number of GFP-positive cells as well as significantly higher transgene expression compared to DOTAP:chol lipoplexes. Representative confocal laser scanning microscopy images of HuH7 cells transfected with DOTAP:chol lipoplexes and AL-A12-containing lipoplexes are shown in Figure 4B,C, respectively. An increased efficiency results in a lower dose of the potentially cytotoxic transfection reagent that needs to be administered while maintaining the same effect and is consequently mitigating side effects of the gene therapy. Moreover, the known composition of these lipoplexes allows for surface modification (*e.g.*, PEGylation), which is difficult to achieve for the proprietary formulation Lipofectamine 3000.

Cytotoxicity of Lipoplex Systems. Figure 4D displays the results of the cell viability assessment. Several aminolipids with aliphatic headgroups and improved transfection efficacy also resulted in enhanced cytotoxic effects (*i.e.*, AL-B to AL-D). Generally, it was observed that aminolipids derived from C₁₂

aldehydes are less toxic than aminolipids derived from C₁₀ aldehydes (Tables S2 and S3). For example, AL-A10 systems showed a toxicity comparable to DOTAP:chol while at the same time having increased DNA delivery efficacy. Interestingly, the lead aminolipid AL-A12 demonstrated lower toxicity across the entire dose range than DOTAP:chol. Up to a concentration of 16 μM total lipid, AL-A12 systems resulted in cell viabilities of approximately 80%. At 64 μM total lipid, AL-A12 still resulted in cell viabilities of up to 50%. These results clearly indicate a lower cytotoxic potential for AL-A12-containing lipoplexes than for DOTAP:chol. Lipoplex systems composed of aminolipids with heterocyclic headgroups caused similar or reduced toxicity. The lowest cytotoxic effects were observed using AL-F10-based lipoplexes, thereby confirming that inclusion of aromatic or heterocyclic rings into a transfection reagent can mitigate cytotoxic effects.^{42–45}

Conclusively, the lead structures from our transfection screening AL-A12 and AL-F10 (most GFP-positive cells and highest MFI) also outperformed the other aminolipids in the cytotoxicity screening assay. This confirms the generally accepted dogma that low cytotoxic side effects are a prerequisite to achieve high transfection rates.⁵³

Assessment of DNA Vector Delivery *In Vivo*. Due to its high transfection efficiency (% transfected cells) and low toxicity *in vitro*, AL-A12 was selected as lead aminolipid for the *in vivo* evaluation in the zebrafish embryo model, a validated *in vivo* tool to assess lipid-based delivery systems.^{39,54–56} To assess the systemic circulation of AL-A12 and DOTAP:chol lipoplexes, the fluorescent lipid 1,1'-dioctadecyl-3,3',3'-tetramethylindodicarbocyanine (DiD) was incorporated as a tracer. To evaluate the utility of developed lipoplexes for *in vivo* gene delivery, lipoplexes entrapped DNA encoding for RFP. Both lipoplex systems were injected intravenously into transgenic zebrafish embryos expressing GFP in their vasculature. Biodistribution and reporter gene expression were analyzed 4 and 24 h post-injection using confocal microscopy (Figure 5).

As expected for cationic systems, both lipoplexes associated with endothelial cells with preference for venous vasculature.⁵⁷ The evaluation of reporter gene expression confirmed the fluorescence distribution patterns. AL-A12-based lipoplexes as well as DOTAP:chol resulted in RFP expression in endothelial cells 4 h post-injection with stronger expression in venous vasculature. Both qualitative confocal imaging and the image analysis confirmed a higher gene expression *in vivo* for AL-A12 compared to DOTAP-based lipoplexes. Further *in vivo* studies are needed to assess the potential to target actively growing tumor blood vessels as shown for other positively charged lipid systems.⁵⁸

CONCLUSIONS

In recent decades, DOTAP:chol lipoplexes have been investigated in several clinical trials for the delivery of DNA vectors. However, none of these studies has advanced to a late clinical stage due to poor outcomes with respect to efficacy. The present study describes the design and one-pot synthesis of short-chain aminolipids enabling incorporation into DOTAP-based lipoplexes to maximize DNA vector delivery. The structure–activity relationship analysis revealed methoxy headgroups to be superior to hydroxy headgroups. Furthermore, C₁₂ lipid tails promote higher transfection efficiencies than C₁₀ tails. The DNA vector transfection ability in HuH7 cells *in vitro* was significantly increased using various

aminolipids (e.g., AL-A12). In addition, incorporation of selected aminolipids clearly mitigated the cytotoxicity. *In vivo* studies in zebrafish embryos showed higher gene expression using the lead lipoplex system based on AL-A12 compared to conventional DOTAP:chol lipoplexes.

In conclusion, our presented one-pot combinatorial synthesis is a versatile approach to create lipid libraries for the development of DNA delivery systems. The combination of DOTAP with short-chain aminolipids promotes efficient DNA vector delivery *in vitro* and *in vivo* as well as reduced cellular toxicity.

Supporting Results

1. Synthesis of Amino Lipids

1.1 Synthesis of *N*-decyl-*N*-(3-methoxypropyl)decan-1-amine (AL-A10)

Figure S1: Chemical structure of *N*-decyl-*N*-(3-methoxypropyl)decan-1-amine (AL-A10).

3-Methoxypropylamine (1.00 eq., 5.00 mmol, 0.51 mL), and decanal (2.20 eq., 11.00 mmol, 2.07 mL) were dissolved in DCM (25 mL) and stirred for 3 h. Sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) was added and the mixture was stirred for 2 days. The product was purified by column chromatography (Silica; EtOAc/MeOH (98:2 V/V) → EtOAc/MeOH (90:10 V/V)) to yield a yellow liquid (702 mg, 1.90 mmol, 38.0 %).

¹H NMR (400 MHz, CDCl₃) δ = 3.47 (t, *J* = 5.5 Hz, 2H), 3.33 (s, 3H), 3.14-3.08 (m, 2H), 3.00-2.95 (m, 4H), 2.16-2.09 (m, 2H), 1.82-1.78 (m, 4H), 1.35-1.27 (m, 28H), 0.89 (t, *J* = 7.0 Hz, 6H) ppm.

¹³C NMR (100 MHz, CDCl₃) δ = 69.3, 58.8, 52.4, 50.5, 31.8, 29.2, 29.0, 26.8, 24.1, 23.0, 22.6, 14.1 ppm.

IR ν = 2924, 2853, 1718, 1579, 1466, 1379, 1256, 1119 cm⁻¹.

HRMS (ESI⁺): *m/z* [M+H]⁺: calculated for [C₂₄H₅₁NO+H]⁺: 370.4048; found: 370.4037.

R_f (EtOAc / MeOH (9:1 V/V)) = 0.34.

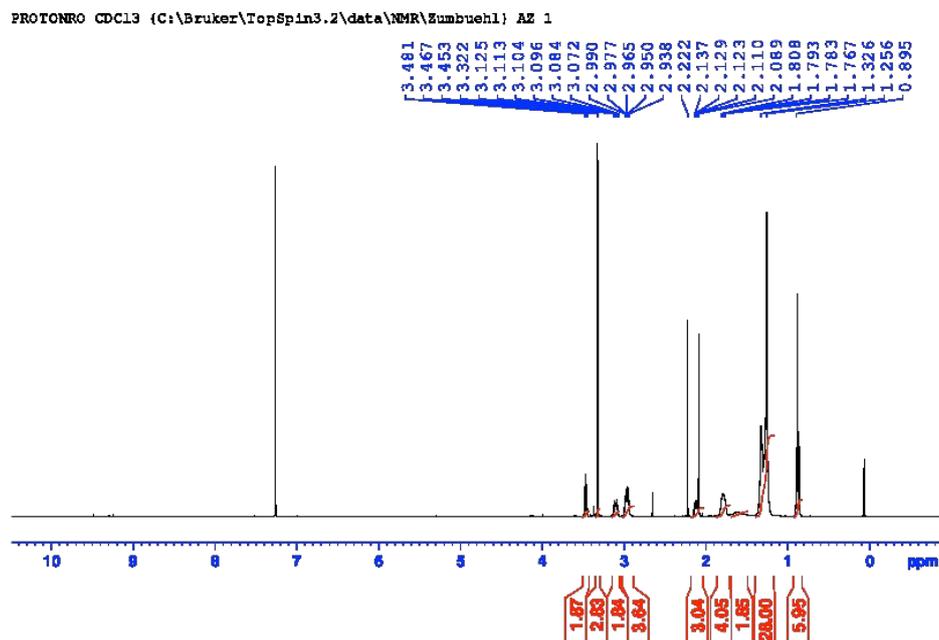

Figure S2: $^1\text{H-NMR}$ of *N*-decyl-*N*-(3-methoxypropyl)decan-1-amine (AL-A10).

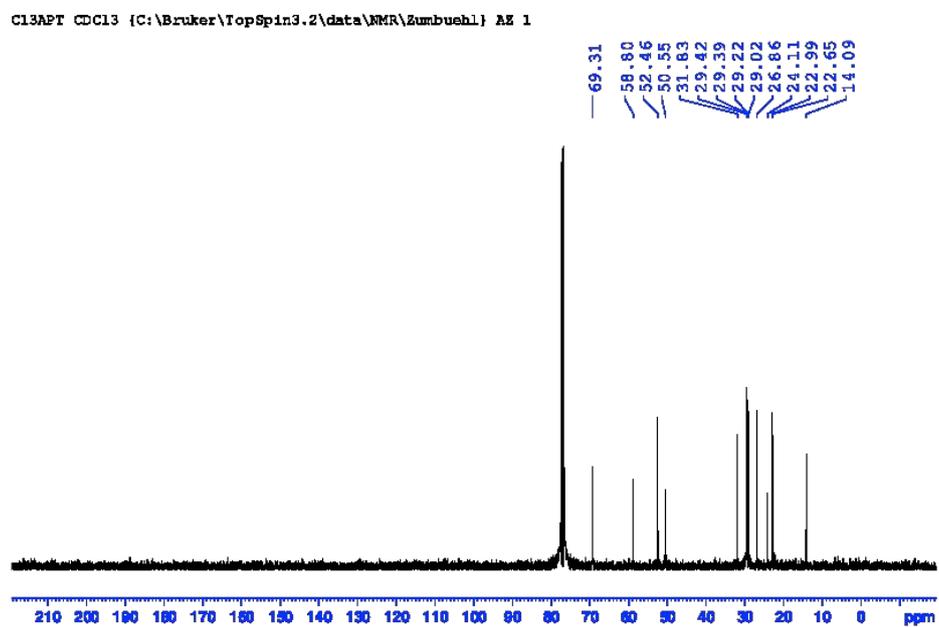

Figure S3: $^{13}\text{C-NMR}$ of *N*-decyl-*N*-(3-methoxypropyl)decan-1-amine (AL-A10).

1.2 Synthesis of *N*-dodecyl-*N*-(3-methoxypropyl)dodecan-1-amine (AL-A12)

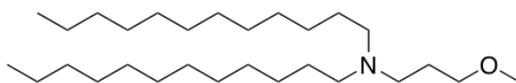

Figure S4: Chemical structure of *N*-dodecyl-*N*-(3-methoxypropyl)dodecan-1-amine (AL-A12).

3-Methoxypropylamine (1.00 eq., 5.00 mmol, 0.51 mL), and lauraldehyde (2.20 eq., 11.00 mmol, 2.44 mL) were dissolved in DCM (25 mL) and stirred for 3 h. Sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) was added and the mixture was stirred for 5 days. The product was purified by column chromatography (silica; DCM/MeOH (98:2 V/V) → DCM/MeOH 90:10 V/V) to yield a yellow, viscous liquid (588 mg, 1.38 mmol, 28 %).

¹H NMR (400 MHz, CDCl₃) δ = 3.49-3.39 (m, 2H), 3.31 (s, 3H), 3.10-3.06 (m, 2H), 2.97-2.93 (m, 3H), 2.05-1.98 (m, 4H), 1.74-1.62 (m, 3H), 1.31-1.25 (m, 36H), 0.87 (t, *J* = 6.9 Hz, 6H) ppm.

¹³C NMR (100 MHz, CDCl₃) δ = 69.5, 58.7, 52.0, 50.1, 31.9, 29.6, 29.6, 29.5, 29.3, 29.1, 26.8, 24.1, 23.0, 22.6, 14.1 ppm.

IR ν = 2923, 2823, 1717, 1567, 1466, 1379, 1251, 1118 cm⁻¹.

HRMS (ESI⁺) : *m/z* [**M+H**]⁺: calculated for [C₂₈H₅₉NO+H]⁺: 426.4674; found: 426.4661.

R_f (DCM / MeOH (9:1 V/V)) = 0.61.

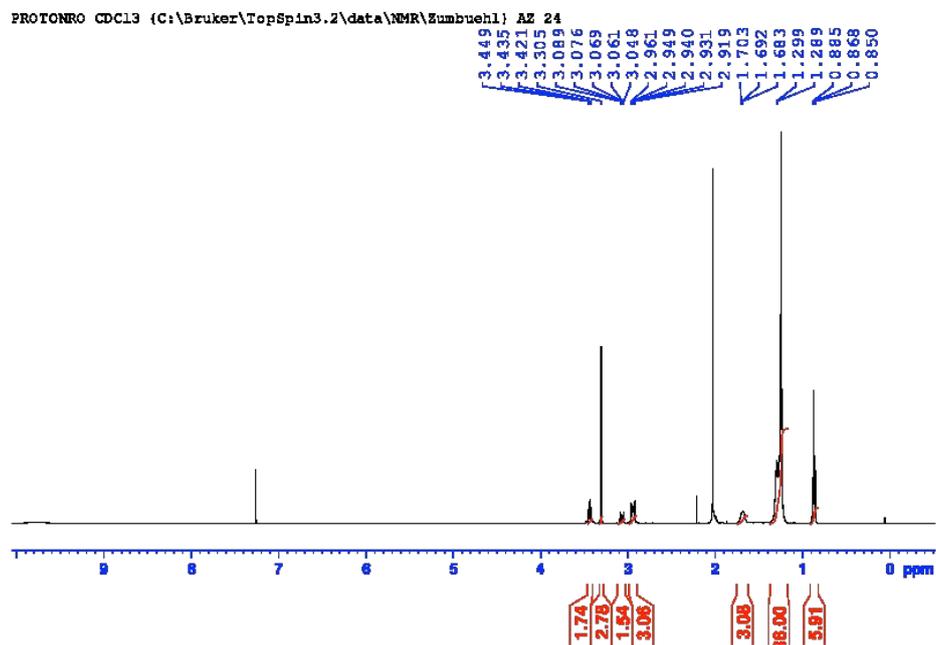

Figure S5: $^1\text{H-NMR}$ of *N*-dodecyl-*N*-(3-methoxypropyl)dodecan-1-amine (AL-A12).

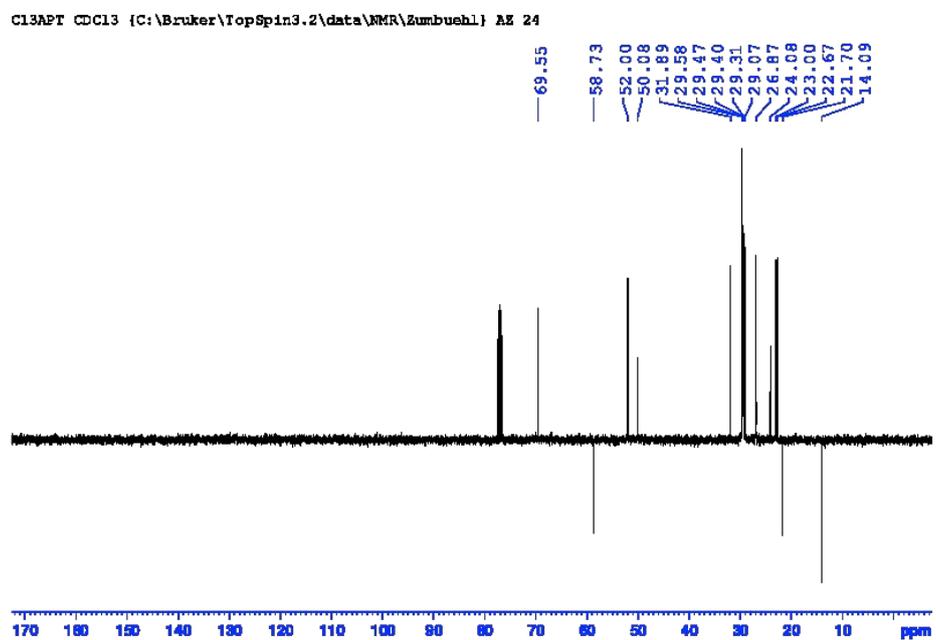

Figure S6: $^{13}\text{C-NMR}$ of *N*-dodecyl-*N*-(3-methoxypropyl)dodecan-1-amine (AL-A12).

1.3 Synthesis of 3-(didecylamino)propan-1-ol (AL-B10)

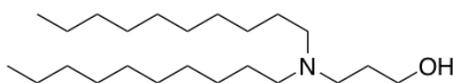

Figure S7: Chemical structure of 3-(didecylamino)propan-1-ol (AL-B10).

3-Amino-1-propanol (1.00 eq., 5.00 mmol, 0.38 mL) and decanal (2.20 eq., 11.00 mmol, 2.07 mL) were dissolved in DCM (25 mL) and stirred for 3 h. Sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) was added and the mixture was stirred for 5 days. The product was purified by column chromatography (silica; DCM/MeOH/H₂O (89:10:1 V/V/V)) to yield a slightly yellow, viscous liquid (1.380 g, 3.88 mmol, 78 %). Aldehyde is not fully reacted off.

¹H NMR (400 MHz, CDCl₃) δ = 3.75-3.72 (m, 2H), 3.14 (t, J =7.2 Hz, 2H), 2.97-2.93 (m, 4H), 1.92 (qui, J =6.2 Hz, 2H), 1.65 (m, 4H), 1.30-1.25 (m, 28H), 0.87 (t, J = 6.8 Hz, 6H) ppm.

¹³C NMR (100 MHz, CDCl₃) δ = 59.0, 51.9, 50.2, 31.8, 29.4, 29.4, 29.2, 29.1, 26.8, 22.9, 22.6, 22.0, 14.0 ppm.

IR ν = 2924, 2855, 1715, 1567, 1467, 1377, 1250, 1062, 1008 cm⁻¹.

HRMS (ESI⁺) : m/z [M+H]⁺: calculated for [C₂₃H₄₉NO+H]⁺: 356.3892; found: 356.3880.

R_f(DCM / MeOH / H₂O, (89:10:1 V/V/V)) = 0.40.

PROTONRO CDCl3 (C:\Bruker\TopSpin3.2\data\NMR\Zumbuehl) AZ 6

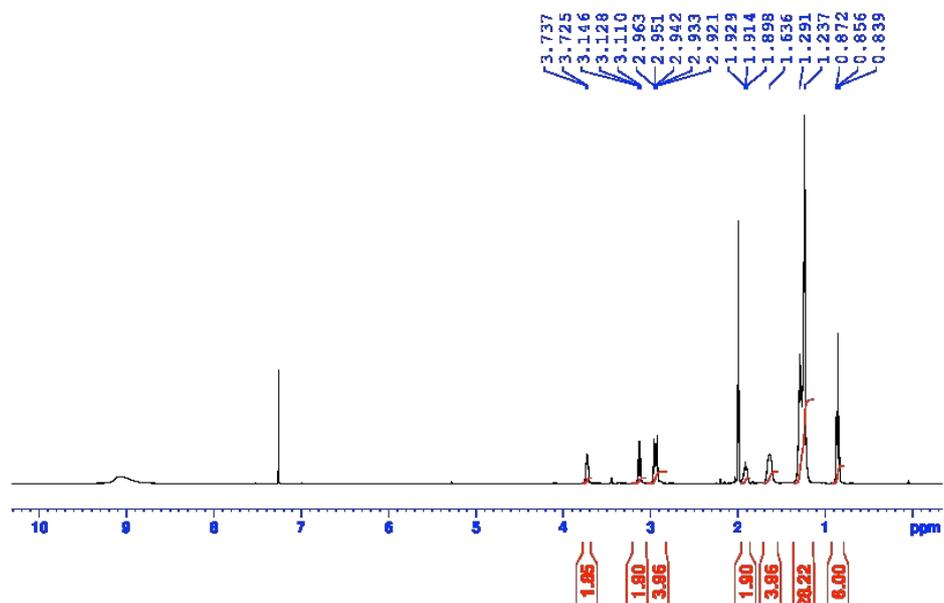

Figure S8: ¹H-NMR of 3-(didecylamino)propan-1-ol (AL-B10).

C13APT CDCl3 (C:\Bruker\TopSpin3.2\data\NMR\Zumbuehl) AZ 6

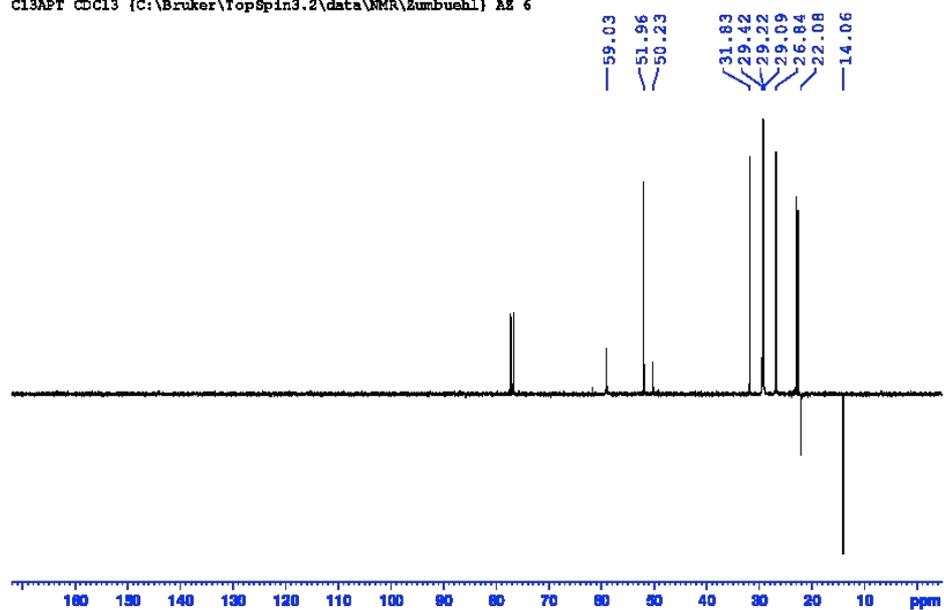

Figure S9: ¹³C-NMR of 3-(didecylamino)propan-1-ol (AL-B10).

1.4 Synthesis of 3-(didodecylamino)propan-1-ol (AL-B12)

Figure S10: Chemical structure of 3-(didodecylamino)propan-1-ol (AL-B12).

3-Amino-1-propanol (1.00 eq., 5.00 mmol, 0.38 mL), lauraldehyde (2.20 eq., 11.00 mmol, 2.44 mL) and sodium triacetoxyborohydride (2.20 eq., 22.00 mmol, 2.33 g) were mixed in DCM and stirred for 2 days.

The product was purified by column chromatography (silica, DCM/MeOH (95:5 V/V)) to yield a yellow liquid (428 mg, 1.04 mmol, 21 %). Aldehyde not fully reacted off.

¹H NMR (400 MHz, CDCl₃) δ = 3.76 (m, 2H), 3.47 (m, 1H), 3.21-3.17 (t, J = 7.2 Hz, 2H), 3.04-3.00 (m, 4H), 1.99-1.93 (q, J = 6.2 Hz, 2H), 1.68 (m, 4H), 1.30-1.24 (m, 36H), 0.88-0.85 (t, J = 6.7 Hz, 6H) ppm.

¹³C NMR (100MHz, CDCl₃) δ = 61.4, 59.0, 52.0, 51.9, 31.8, 29.5, 29.3, 29.3, 29.0, 26.7, 26.3, 22.8, 22.6, 21.1, 14.0 ppm.

IR ν = 2924, 2855, 1713, 1379, 1237, 1008 cm⁻¹.

HRMS (ESI⁺) : m/z [M+H]⁺: calculated for [C₂₇H₅₇NO + H]⁺: 412.4513; found : 412.4512

R_f (DCM/MeOH (95:5 V/V)): 0.67.

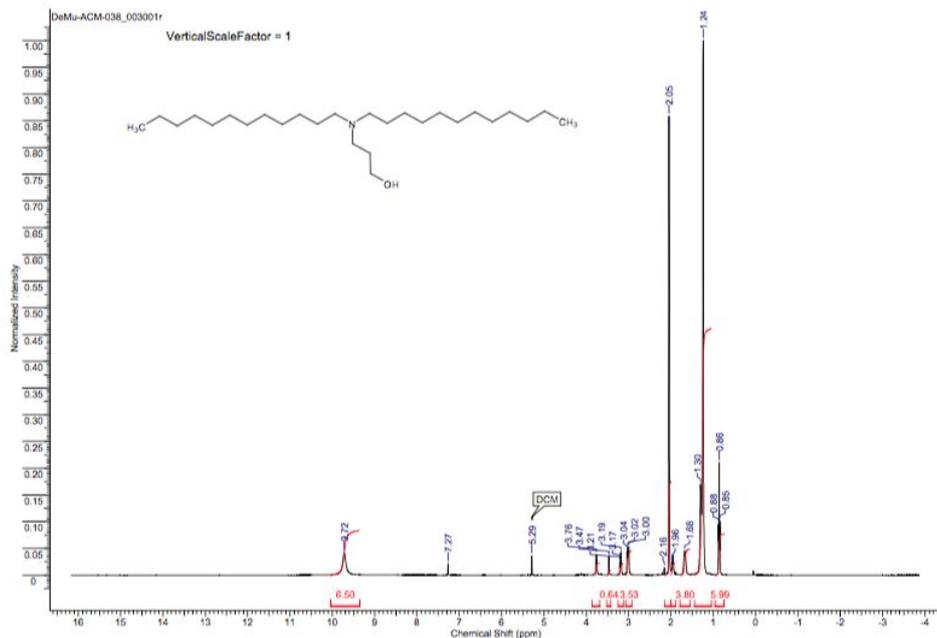

Figure S11: $^1\text{H-NMR}$ of 3-(didodecylamino)propan-1-ol (AL-B12).

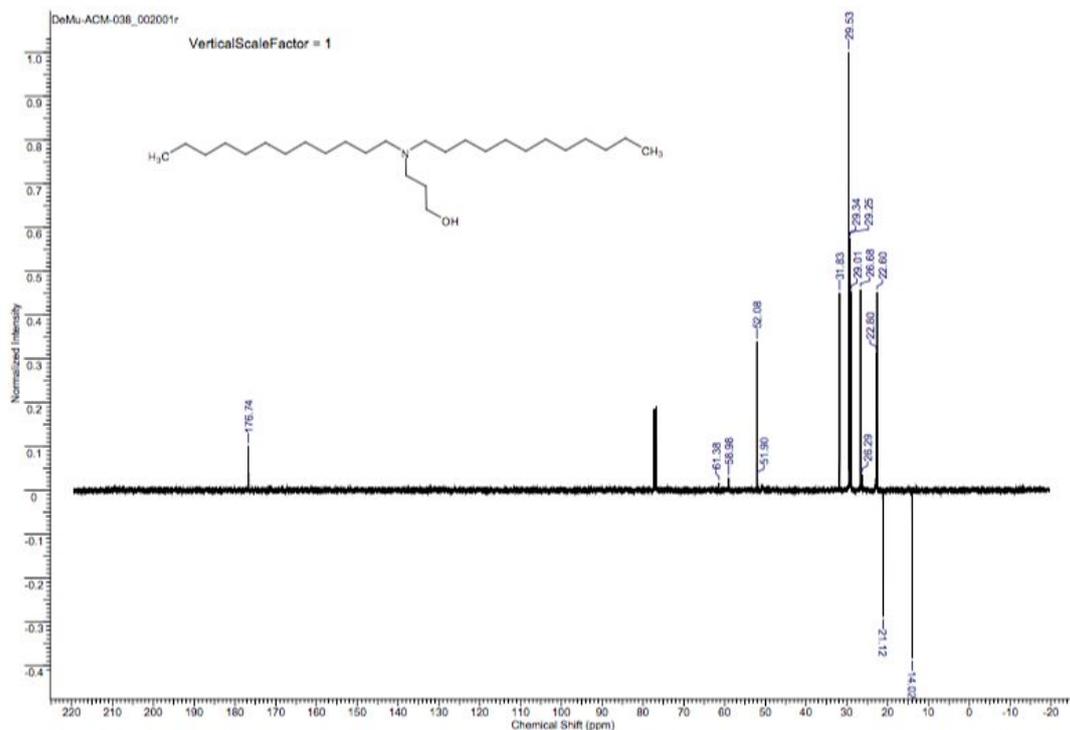

Figure S12: $^{13}\text{C-NMR}$ of 3-(didodecylamino)propan-1-ol (AL-B12).

1.5 Synthesis of 3-(didecylamino)propane-1,2-diol (AL-C10)

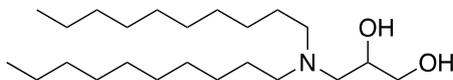

Figure S13: Chemical structure of 3-(didecylamino)propane-1,2-diol (AL-C10).

(±)-3-Amino-1,2-propanediol (1.00 eq., 5.00 mmol, 0.51 mL), decanal (2.20 eq, 11.00 mmol, 2.07 mL) and sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) were mixed in DCM and stirred for 2 days. The product was purified by column chromatography (silica; EtOAc/MeOH (98:2 V/V) → EtOAc/MeOH (90:10 V/V)) to yield a yellow liquid (773 mg, 2.081 mmol, 42 %).

NMR data still showed impurities after several purification steps.

HRMS (ESI⁺) : m/z [M+H]⁺: calculated for [C₂₃H₄₉NO₂ + H]⁺: 372.3836; found : 372.3831

R_f (EtOAc/MeOH (90:10 V/V)): 0.25.

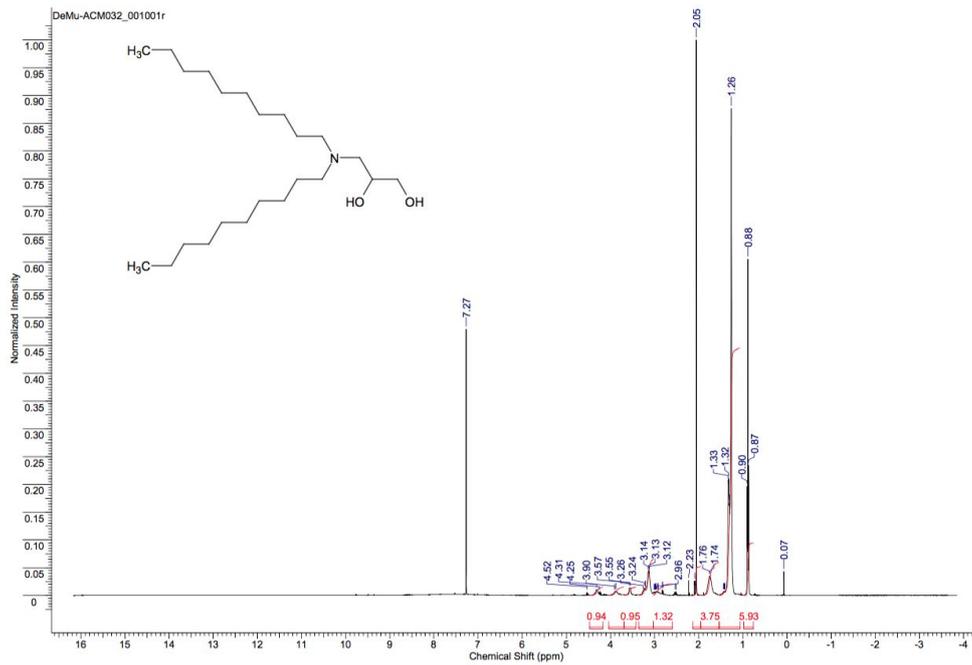

Figure S14: $^1\text{H-NMR}$ of 3-(didecylamino)propane-1,2-diol (AL-C10).

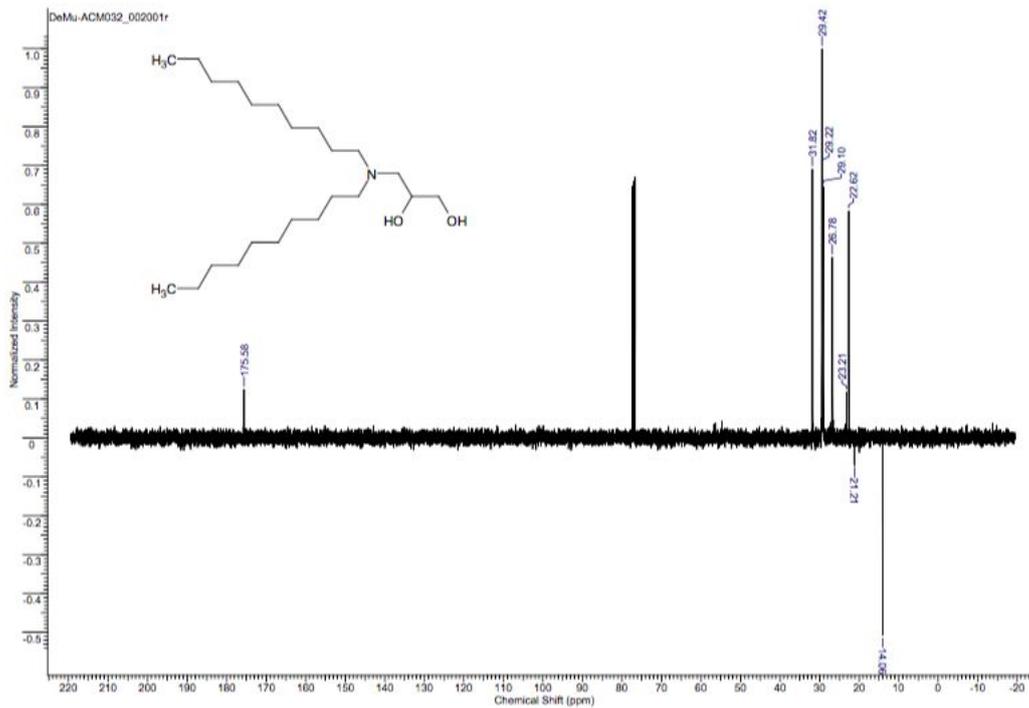

Figure S15: $^{13}\text{C-NMR}$ of 3-(didecylamino)propane-1,2-diol (AL-C10).

1.6 Synthesis 3-(didodecylamino)-1,2-propanediol (AL-C12)

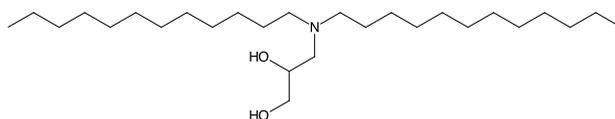

Figure S16: Chemical structure of 3-(didodecylamino)-1,2-propanediol (AL-C12).

(±)-3-Amino-1,2-propanediol (1.00 eq., 5.00 mmol, 0.51 mL), lauraldehyde (2.20 eq., 11.00 mmol, 2.44 mL) and sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) were mixed in DCM and stirred for 2 days. The product was purified by column chromatography (silica; DCM/MeOH (98:2 V/V)). The yield was too low to be determined, but still sufficient for characterization by NMR and HRMS.

¹H NMR (600 MHz, CDCl₃) δ = 4.17-4.11 (m, 1H), 3.73-3.67 (m, 1H), 3.62-3.56 (m, 1H), 3.18-2.93 (m, 5H), 1.75-1.57 (m, 2H), 1.36-1.20 (m, 38H), 0.91-0.85 (m, 6H) ppm.

¹³C NMR (150 MHz, CDCl₃) δ = 66.8, 64.7, 57.3, 54.2, 32.1, 29.8, 29.8, 29.7, 29.6, 29.5, 29.4, 27.1, 23.8, 22.9, 14.3 ppm.

HRMS (ESI⁺): m/z [M+H]⁺: calculated for [C₂₇H₅₇NO₂ + H]⁺: 428.4462; found: 428.4462.

1.10 Synthesis of (Benzyl)didecylamine (AL-F10)

S19

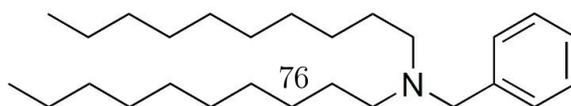

Figure S28: Chemical structure of (Benzyl)didecylamine (AL-F10).

Benzylamine (1.00 eq., 5.00 mmol, 0.55 mL), and decanal (2.20 eq., 11.00 mmol, 2.07 mL) were dissolved in DCM (25 mL) and stirred for 3 h. Sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) was added and the mixture was stirred for 2 days. The product was purified by column chromatography (Silica; EtOAc/MeOH (98:2 V/V) → EtOAc/MeOH (90:10 V/V)) to yield a dark yellow liquid (666 mg, 1.72 mmol, 34.4 %).

$^1\text{H-NMR}$ (400 MHz, CDCl_3): δ = 7.27 – 7.10 (m, 5H), 3.46 (s, 2H), 2.36 – 2.26 (m, 4H), 1.45 – 1.31 (m, 4H), 1.17 (s, 28H), 0.81 (t, J = 6.8 Hz, 6H) ppm.

$^{13}\text{C-NMR}$ (100 MHz, CDCl_3): δ = 140.5, 129.0, 128.2, 126.7, 58.8, 54.0, 32.1, 29.83, 29.77, 29.75, 29.5, 27.5, 27.2, 22.8, 14.3 ppm.

HRMS (ESI $^+$): m/z [M+H] $^+$: calculated for $[\text{C}_{27}\text{H}_{49}\text{N} + \text{H}]^+$: 388.3938; found : 388.3933.

R_f (DCM:MeOH (92:8 V/V)): 0.94.

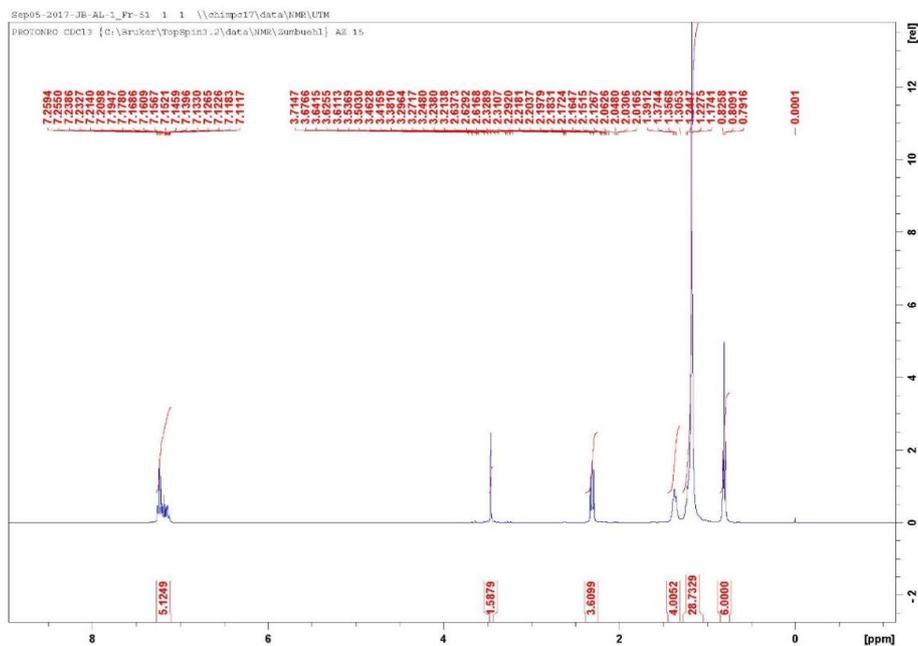

Figure S29: $^1\text{H-NMR}$ of (Benzyl)didecylamine (AL-F10).

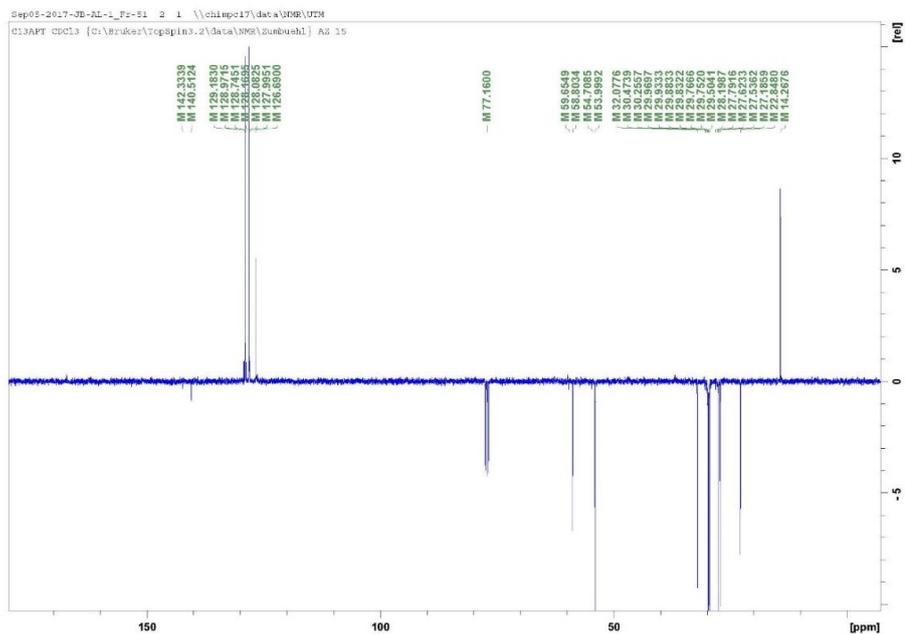

Figure S30: ^{13}C -NMR of (Benzyl)didecylamine (**AL-F10**).

1.11 Synthesis of [(1*H*-Imidazol-2-yl)methyl]didecylamine (**AL-G10**)

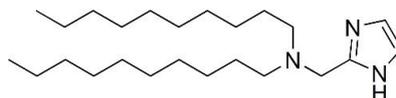

Figure S31: Chemical structure of [(1*H*-Imidazol-2-yl)methyl]didecylamine (**AL-G10**).

2-(Aminomethyl)imidazole dihydrochloride (1.00 eq., 5.00 mmol, 0.85 g), and decanal (2.20 eq., 11.00 mmol, 2.07 mL) were dissolved in DCM (25 mL) and stirred for 3 h. Sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) was added and the mixture was stirred for 2 days. The product was purified by column chromatography (Silica; EtOAc/MeOH (98:2 V/V) → EtOAc/MeOH (90:10 V/V)) to yield a yellow liquid (1.36 g, 3.59 mmol, 71.9 %).

¹H-NMR (400 MHz, CDCl₃): δ = 11.23 (br s, 2H), 7.01 – 6.93 (m, 2H), 5.22 (s, 1H), 4.39 (s, 1H), 3.58 – 3.55 (m, 1 H), 2.86 – 2.81 (m, 2H), 1.98 (br s, 4H), 1.58 – 1.46 (m, 3H), 1.18 (br s, 28H), 0.83 – 0.79 (m, 6H) ppm.

The integrals are not fitting well due to impurities which could not be removed by chromatography.

Residual solvent peaks were found for DCM (5.33 ppm) and EtOAc 1.26 (s), 2.05 (t), 4.12 (q)

¹³C-NMR (100 MHz, CDCl₃): δ = 138.1, 122.9, 63.1, 52.9, 49.5, 37.7, 34.6, 32.9, 32.0, 32.0, 29.7, 29.7, 29.6, 29.6, 29.6, 29.5, 29.4, 29.3, 29.2, 29.0, 27.3, 27.3, 26.9, 25.9, 23.4, 22.8, 22.2, 14.2 ppm.

HRMS (ESI⁺): m/z [M+H]⁺: calculated for [C₂₄H₄₇N₃ + H]⁺: 378.3843; found : 378.3843.

R_f(DCM:MeOH (92:8 V/V)): 0.64.

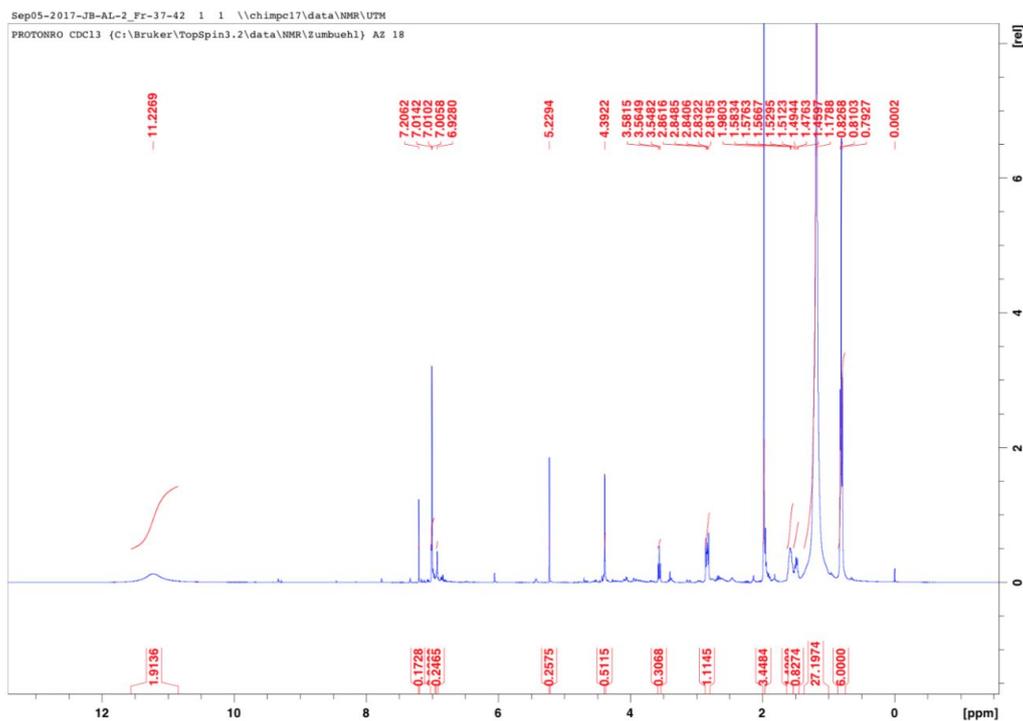

Figure S32: ¹H-NMR of [(1H-Imidazol-2-yl)methyl]didecylamine (AL-G10).

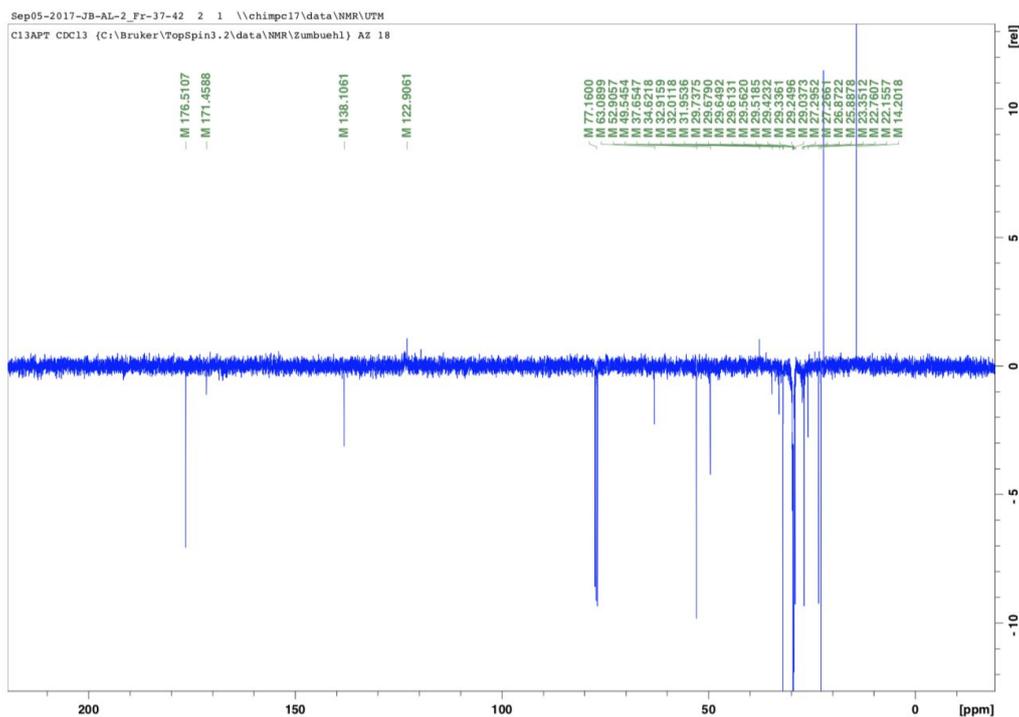

Figure S33: ^{13}C -NMR of [(1*H*-Imidazol-2-yl)methyl]didecylamine (**AL-G10**).

1.12 Synthesis [(4-Pyridyl)methyl]didecylamine (**AL-H10**)

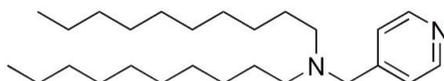

Figure S34: Chemical structure of [(4-Pyridyl)methyl]didecylamine (**AL-H10**).

4-(Aminomethyl)pyridine (1.00 eq., 5.00 mmol, 0.51 mL), and decanal (2.20 eq., 11.00 mmol, 2.07 mL) were dissolved in DCM (25 mL) and stirred for 3 h. Sodium triacetoxyborohydride (2.20 eq., 11.00 mmol, 2.33 g) was added and the mixture was stirred for 2 days. The product was purified by column chromatography (Silica; EtOAc/MeOH (98:2 V/V) \rightarrow EtOAc/MeOH (90:10 V/V)) to yield a brown liquid (1.75 g, 4.51 mmol, 90.1 %). The spectrum still shows small acetic acid contaminations at approx. 2.1 ppm (^1H -NMR), 175 ppm, and 21 ppm (both ^{13}C -NMR) that could not be removed with column chromatography.

¹H-NMR (400 MHz, CDCl₃): δ = 8.54 – 8.49 (m, 2H), 7.32 – 7.29 (m, 2H), 3.56 (s, 2H), 2.44 – 2.36 (m, 4H), 1.49 – 1.39 (m, 4H), 1.24 (s, 28H), 0.87 (t, *J* = 6.8 Hz, 6H) ppm.

¹³C-NMR (100 MHz, CDCl₃): δ = 150.3, 149.1, 124.0, 57.8, 54.2, 32.0, 29.8, 29.71, 29.66, 29.5, 27.5, 27.0, 22.8, 14.2 ppm.

HRMS (ESI⁺): *m/z* [M+H]⁺: calculated for [C₂₆H₄₈N₂ + H]⁺: 389.3890; found : 389.3890.

R_f(DCM:MeOH (92:8 V/V)): 0.78.

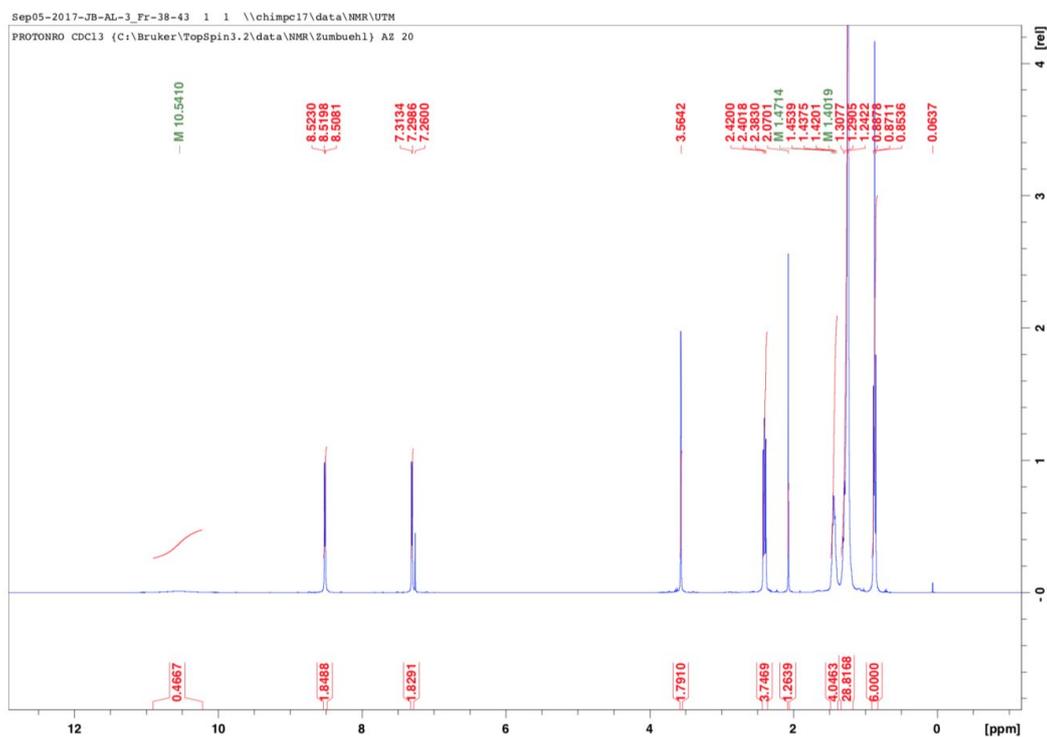

Figure S35: ¹H-NMR of [(4-Pyridyl)methyl]didecylamine (AL-H10).

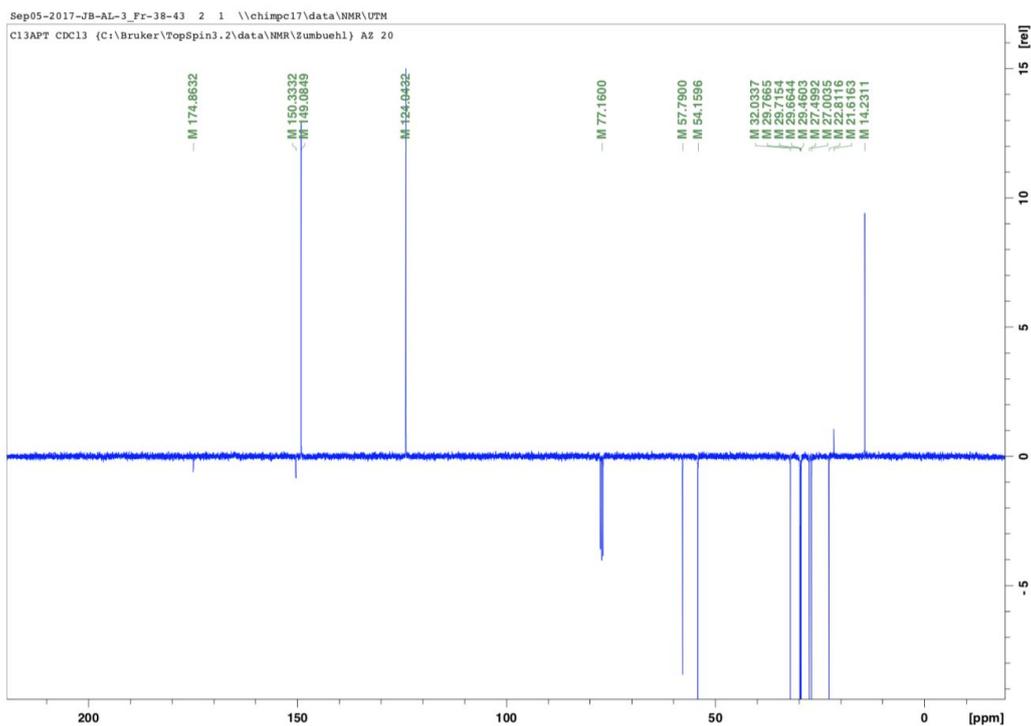

Figure S36: ^{13}C -NMR of [(4-Pyridyl)methyl]didecylamine (AL-H10).

2. *In vitro* experiments

2.1 Transfection experiments

Table S1: Results of transfection experiments for aminolipid- and DOTAP:chol-based lipoplexes.

Substance	Setting	GFP positive cells [%]	MFI [RFU]
AL-A10	1 μg DNA, 1:1 ratio	7.7	801
	2 μg DNA, 1:1 ratio	28.7	1033
AL-A12	1 μg DNA, 1:1 ratio	10.3	785
	2 μg DNA, 1:1 ratio	31.5	1606
AL-B10	1 μg DNA, 1:1 ratio	5.0	384
	2 μg DNA, 1:1 ratio	11.5	928

DOTAP:chol	78.4 ± 1.5	73.1 ± 1.1	65.3 ± 0.1	22.0 ± 0.2	17.4 ± 1.1

2.3 Structure-Activity-Relationship

The SAR was done for aminolipids AL-A10, AL-A12, AL-B10, AL-B12, and DOTAP:chol. A total of three independent measurements with three replicates each was done to obtain the data necessary for statistical evaluation. Statistical evaluation was carried out using Origin 2018 Pro (see Materials and Methods).

2.3.1 Results of the Structure-Activity-Relationship experiments

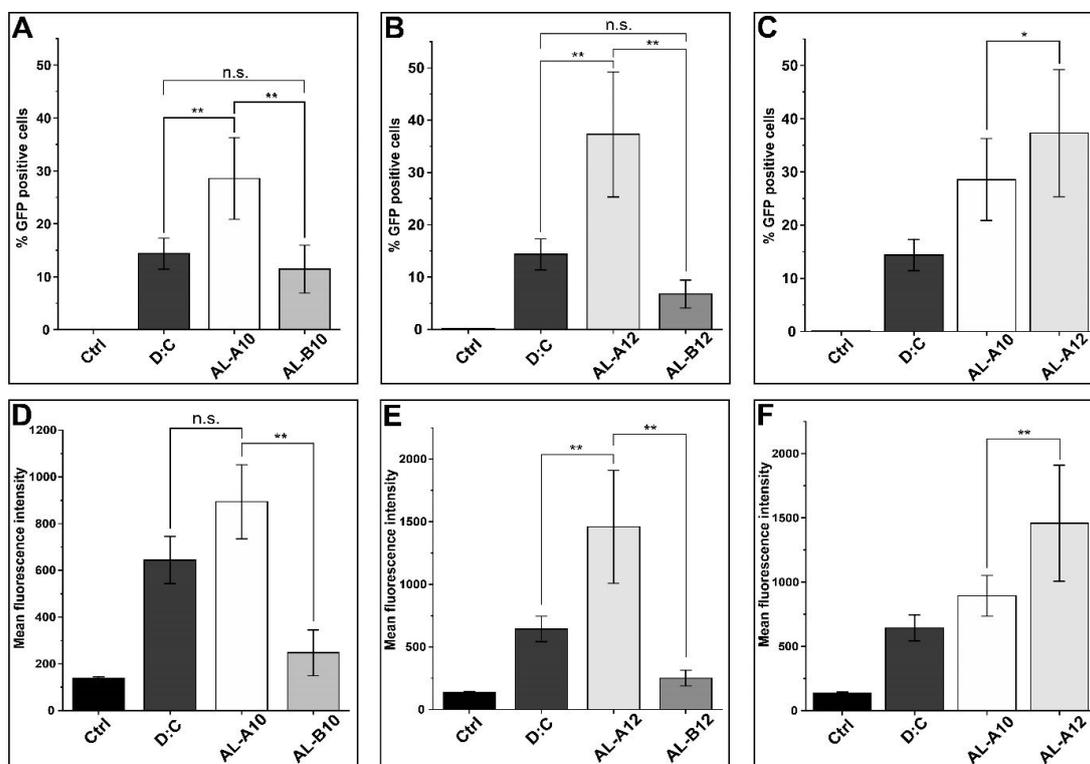

Figure S37: Structure-Activity-Relationship for the most promising aminolipids AL-A10, AL-A12, AL-B10, AL-B12, as well as DOTAP:chol. The graph shows the influence of the headgroup on transfection efficiency (A, B) and transgene expression (D, E) when the tail length stays constant and the influence of the tail length on transfection efficiency (C) and transgene expression (F) when the headgroup stays constant. Methoxy headgroups are superior to hydroxy headgroups ($p < 0.001$) and C_{12} tails are superior to C_{10} tails in both, transfection efficiency ($p < 0.1$) and transgene expression ($p < 0.001$). The data were obtained from three independent measurements with three replicates each. * $p < 0.1$, ** $p < 0.001$.

2.3.2 ANOVA Tables for GFP ($p < 0.1$)

Table S4: Descriptive statistics for the one way ANOVA for GFP ($p < 0.1$). AL 1 corresponds to AL-A10, AL 2 corresponds to AL-A12, AL 3 corresponds to AL-B10, and AL 4 corresponds to AL-B12.

	N Analysis	N Missing	Mean	Standard Deviation	SE of Mean
DOTAP/Chol 1 ug	8	1	6.0	0.7	0.3
AL 1 1 ug	9	0	7.9	1.9	0.6
AL 2 1 ug	9	0	11.2	4.2	1.4
AL 3 1 ug	9	0	4.7	2.0	0.7

2.3.6 Outlier Detection

Table S 20: Outlier detection for GFP at 1µg/mL DNA and a lipid-to-DNA ratio of 1. Outliers (red) were defined as values larger than the upper fence or lower than the lower fence and were excluded from analysis. Upper fence is defined by $Q3 + 1.5 \times \text{IQR}$ and lower fence is defined by $Q1 - 1.5 \times \text{IQR}$. Only one outlier could be identified.

Characterization and Optimization of Lipoplexes: How to standardize Assays and avoid Pitfalls

Jonas Buck, Dominik Witzigmann, Susanne H. Schenk, Tomaz Einfalt, Ludovit Zweifel, Hiu-Man Grisch-Chan, Beat Thöny, Jörg Huwyler

Manuscript ready for submission.

Highlights: Interactions between DNA and nanoparticles are still poorly understood to this day. Usually, DNA and lipid-based nanoparticles are combined based on calculations and applied to cultured cells or animal models assuming that the calculations reflect the actual conditions. In our opinion, this approach is flawed because losses during preparation cannot be accounted for. In this publication, we propose the application of fluorescence cross-correlation spectroscopy (FCCS) to determine the interactions between DNA and nanoparticles. The results showed that the interactions are qualitatively and quantitatively different among the three used transfection reagents. We therefore recommend that interactions between DNA and nanoparticles should be determined for each individual formulation to reduce artifacts and to draw conclusions based on actual data rather than calculations.

Characterization and Optimization of Lipoplexes: How to standardize Assays and avoid Pitfalls

Abstract

Gene therapy aims to introduce nucleic acids into cells. Besides viral delivery, one of the most common approaches to achieve this is the use of lipid-based nanoparticles. Nucleic acids and nanoparticles are combined based on defined mixing ratios and it is generally assumed that the calculated concentrations are identical to the actual concentrations in the preparation prior to application. Herein, we apply fluorescence cross-correlation spectroscopy (FCCS) to quantify nucleic acid and nanoparticle interactions. Using FCCS, we could show that calculated concentrations do not necessarily reflect actual concentrations. The disparity was higher for a commercial formulation with unknown composition compared to self-prepared formulations. We conclude that comparisons between formulations may be misleading if they are solely based on theoretical assumptions and not on experimental data. We therefore recommend investigating interactions between nanoparticles and nucleic acids for each formulation individually to avoid this common pitfall in non-viral gene delivery.

Introduction

Gene therapy represents an attractive therapeutic option to treat various diseases. However, many aspects of molecular mechanisms involved in successful transfection of target tissues are still poorly understood.^{1,2} In the field of lipid-based non-viral gene delivery, efforts are ongoing to identify lipid or lipid-like molecules, which can be used to promote successful transfer of nucleic acids into cells. Despite some setbacks, many formulations that promote high gene delivery efficiencies both *in vitro* and *in vivo* were developed in the recent years.³⁻⁷ In many instances, researchers did thereby use an empiric approach to optimize lipid based formulations. In addition to formulations developed in the academic environment several private companies entered the market with ready-to-use formulations (such as formulations of the Lipofectamine family) that can act as a reference system to compare different formulations with each other.^{1,8,9} These commercial transfection reagents have been used by thousands of researchers so far and still see widespread application as standard

formulations for *in vitro* trials despite the fact that their precise composition is not disclosed.^{10–13} Therefore, as a pragmatic approach, nucleic acids and transfection reagent are diluted separately in an appropriate buffer, combined, incubated to allow for spontaneous complexation, and finally added to target cells. It is generally assumed, that the formed lipoplexes (complexes of lipid-based transfection reagent and nucleic acid) contain the calculated amount of added ingredients. Furthermore, mixing ratios between different components of the system are believed to be precisely defined and key to a further optimization of the experimental system.^{14,15} In our opinion, this procedure leads to artefacts because the formation of lipoplexes can be influenced by many factors such as the type of nucleic acid,¹⁶ the type of lipid based constituents and the used amounts of lipoplexes.^{17–19} There are some publications in which the amount of delivered nucleic acid per cell is quantified via PCR.^{20–24} However, in most cases researchers just assume that the calculated amount of nucleic acids or lipoplexes used corresponds to actual quantities delivered to the target cells. We believe that the outlined approach is flawed. Transfection efficiency is not solely a function of the amount of DNA added. Furthermore, mixing ratios of all components of the used systems should be experimentally confirmed since we cannot exclude unspecific binding of lipids or lipoplexes to surfaces.

It was therefore the aim of the present project to develop a fluorescence-based method that would allow us to investigate DNA – nanoparticle interactions. Fluorescence cross-correlation spectroscopy (FCCS) was thereby identified as a promising approach to study nucleic acid-nanoparticle interactions and lipoplex formation.²⁵ In contrast to quantitative PCR methods, flow cytometry, or confocal microscopy, a quantitative assessment of DNA and particle interactions is possible by this method. Using FCCS, the diffusion dynamics of labeled particles within a confined confocal volume can be monitored. Based on diffusion times and signal amplitudes, the size and concentration of particles can be determined [ref]. Moreover, FCCS experiments can provide valuable insights into DNA binding patterns and amounts of labeled reagents. As a model system, small minicircle DNA (1.4 kb) and conventional parental plasmid DNA (5.4 kb) was used. Both DNA moieties were complexed with a cationic lipid (1,2-dioleoyl-3-trimethylammonium-propane, DOTAP) formulation, an ionizable lipid dilinoleylmethyl-4-dimethylaminobutyrate (DLin-MC3-DMA) formulation, as well as with a commercially available transfection reagent (Lipofectamine 3000). A design of experiment (DoE) approach was chosen to obtain data about gene delivery efficiency and transgene expression levels. The results of the FCCS measurements provided new insights in the mechanisms of interaction between DNA and lipid nanoparticles and allowed us to identify potential sources of artefacts.

Materials and Methods

Nanoparticle preparation

Lipofectamine 3000 (Invitrogen, Life Technologies, Zug, Switzerland) was used as provided by the manufacturer. DOTAP:cholesterol nanoparticles were both, extruded and prepared using microfluidics, whereas DLin-MC3-DMA nanoparticles were prepared employing a microfluidics approach only (NanoAssemblr, Precision Nanosystems, Vancouver, Canada) because extrusion was not possible with the used settings.

Extrusion

DOTAP (Corden Pharma Switzerland LLC, Liestal, Switzerland) and cholesterol (Sigma-Aldrich Co, St. Louis, MO, USA) were combined at a 1:1 ratio (mol%) using the respective ethanolic stock solutions.

The lipid film was then dried using nitrogen. Afterwards, the dried lipid film was subjected to vacuum for at least 48 h. At the day of extrusion, the dried lipid film was rehydrated with 5% glucose (Roth AG, Switzerland) solution at constant stirring and heating to 60 °C for 10 min. The rehydrated lipid film was then vortexed for 30 s and subjected to 5 freeze-thaw cycles (5 min each) using dry ice and a water bath (60 °C). After freeze-thaw, the lipid film was left for 3 h and was subsequently extruded 15 times through a 100 nm polycarbonate membrane (Whatman Nuclepore Track-Etched Membranes, GE Healthcare Life Sciences, Buckinghamshire, UK) using a hand extruder (Avanti Mini Extruder, Avanti Polar Lipids Inc, AL, USA). The size and the PDI of the resulting nanoparticles were determined using a DLS (Delsa Nano C Particle Analyzer, Beckman Coulter, Inc, Indianapolis, IN, USA) and extrusion was repeated if necessary to obtain nanoparticles with a size range of 90 – 110 nm and a PDI > 0.2.

Microfluidics

DOTAP and cholesterol (1:1), or DLin-MC3-DMA, cholesterol, and DOPC were combined at a ratio of 5:4:1 (mol%) from their ethanolic stock solutions. The lipid film was again dried using nitrogen and vacuum as described for DOTAP/cholesterol nanoparticles. At the day of nanoparticle preparation, the lipid components were redissolved in a given volume of ethanol and loaded into a syringe. Using the NanoAssembler, the lipid fraction was combined with 5% glucose solution (DOTAP:chol) or 20 mM acetate buffer pH 4.0 (DLin-MC3-DMA) at a 1:3 ratio in a microfluidic cartridge. The resulting nanoparticles' size and PDI was determined using a DLS and the nanoparticles were subjected to dialysis overnight against 20 mM acetate buffer pH 4.0 (5% glucose in the case of DOTAP:chol) to remove the remaining ethanol. The resulting nanoparticles were used for transfection experiments. A pH below 4.0 was mandatory because DLin-MC3-DMA-based nanoparticles aggregated and precipitated in higher pH media due to the lacking stabilizing effect of PEG.²⁶

Nanoparticle/DNA complex preparation

Nanoparticle/DNA complexes were prepared in 5% glucose solution. Lipofectamine 3000 was combined with DNA at indicated ratios according to the manufacturer's protocol. DOTAP:cholesterol and DLin-MC3-DMA nanoparticles were diluted in separate tubes as was DNA. The diluted samples were vortexed and spun down for a short time frame and the content of the tube containing the diluted DNA was added to the tube containing the diluted nanoparticles. The resulting nanoparticle/DNA formulations were again vortexed and spun down quickly and left for 30 min for complex maturation. After complex maturation, the samples were added to the cells.

Transfection

All cell lines were seeded in poly-D-lysine-coated 24-well plates (TPP Tissue Culture Testplate 24, TPP Techno Plastic Products AG, Trasadingen, Switzerland) at a seeding density of 5×10^4 cells per well. Cells were maintained in Dulbecco's modified Eagle's medium (DMEM, Sigma-Aldrich Co, St. Louis, MO, USA), supplemented with 10% fetal calf serum (FCS, BioConcept, Allschwil, Switzerland), as well as penicillin (100 units/mL), and streptomycin (100 µg/mL) (both from Sigma-Aldrich Co, St. Louis, MO, USA). The total volume of medium was 1 mL. Cells were then left to attach and grow for 24 h in humidified 5% CO₂ at 37 °C. The prepared nanoparticle/DNA formulations (total volume of 50 µL) were then added to the cells. The cells were incubated with the nanoparticle/DNA formulations for indicated time frames without changing the medium.

Flow cytometry

The cells were washed with 1 mL D-PBS (Sigma-Aldrich Co, St. Louis, MO, USA) and detached at indicated timepoints using 200 µL 0.25% Trypsin/EDTA (Invitrogen, Life Technologies, Zug,

Switzerland). The cells were collected and centrifuged for 5min at 200 x g. Excess medium was removed by aspiration and the cell pellet was resuspended in FACS buffer (D-PBS supplemented with 1% FCS, 0.5% EDTA, and 0.5% sodium azide, Sigma-Aldrich Co, St. Louis, MO, USA), transferred to FACS tubes and stored on ice. Flow cytometry was done using a FACS Canto II flow cytometer (Becton Dickinson, San Jose, CA) and the stopping gate was 10.000 cells. The cells were gated to obtain singlets and the percentage of GFP-positive cells (transfection efficiency) and the median fluorescence intensity (transgene expression, MFI) were recorded after excitation at 488 nm. The fluorescence signal of cells expressing GFP was detected in fluorescence channel FL1 (505LP – 530/30).. Further analysis of the obtained data was done using FlowJo Vx software (TreeStar, Ashland, OR, USA).

Design of experiment (DoE)

To screen minicircle DNA and parental plasmid DNA for transfection efficiency and transgene expression, a design of experiment (DoE) approach was applied. A full factorial (2 level) interaction model design was set up using the software MODDE v. 9.0.0.0. The design consisted of the three factors DNA concentration, lipid-to-DNA ratio, and the type of DNA molecule (minicircle DNA vs. parental plasmid DNA) and the two responses transfection efficiency (%GFP positive cells) and transgene expression (MFI). A total of 30 experimental runs per model was carried out to collect the data necessary to generate the model. Models were generated for each cell line and transfection reagent. The resulting data was log transformed where necessary (see supporting information Table S1) and data points with deviations $\geq \pm 3$ SD in the normal probability plot of the Y-residuals were excluded (see supporting information Table S1). Interaction terms were kept to a minimum and were sequentially excluded to increase the model fit and predictability.

Cytotoxicity

Cytotoxicity of lipid nanoparticles alone and lipid nanoparticles combined with DNA was determined by means of MTT assay. Briefly, 50000 cells per mL were seeded in a 96-well plate (TPP Tissue Culture Testplate 96F, TPP Techno Plastic Products AG, Trasadingen, Switzerland) which was previously treated with poly-D-lysine. The final volume of the medium containing the cells was 200 μ L per well resulting in 10000 cells seeded per well. After 24 hours, cells were treated with either nanoparticles alone or nanocomplexes comprising of LNPs and DNA at indicated concentrations. 24 hours later, the medium was aspirated and replaced by medium containing 0.5 mg/mL 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT, Carl Roth, Karlsruhe, Germany). After an incubation period of 2 hours (37°C, 5% CO₂), the medium containing the MTT reagent was aspirated. The insoluble formazan crystals formed within the cells were solubilized using a mixture of 3% SDS in H₂O and 40 mM HCl in isopropanol (1:6, V/V). The plate was then placed on a shaker for 2 hours to completely dissolve the formazan crystals. Following solubilization, absorption was measured using a 96-well plate reader (SpectraMax M2e Microplate Reader, Molecular Devices LLC, San Jose, CA, USA) at 570 nm (formazan signal) and 670 nm (background).

Transmission electron microscopy (TEM)

To acquire TEM images of the nanocomplexes, samples were prepared on copper grids. Briefly, the sample was put on the grip for 1 min and stained twice with 2% uranylacetate solution. Afterwards, the grid was washed twice with ddH₂O and left at RT for 24 hours until completely dried. TEM images were then acquired on a CM-100 electron microscope (Philips, Eindhoven, Netherlands).

Fluorescence cross-correlation spectroscopy (FCCS)

Labeling of LNPs was done by inclusion of 0.1 mol-% of 1,1'-dioctadecyl-3,3',3'-tetramethylindocarbocyanine perchlorate (DiI) in the formulation prior to extrusion. For Lipofectamine 3000, DiI was added in the same amount to the ready-to-use formulation. No purification step was taken because first, the DiI dye is highly fluorescent in lipophilic environments whereas it shows only weak fluorescence in hydrophilic environments²⁷, and second, free dye can be easily distinguished from dye bound to nanoparticles in FCCS measurements. DNA was labeled using the Cy5 Label IT[®] kit according to the manufacturer's protocol. The labeled DNA sample was subsequently purified using the purification columns provided with the kit. FCCS measurements were carried out according to the procedure described by Zelmer et al. on an Olympus IX73 inverted microscope equipped with a 1.2 N.A. water-immersion 60× superapochromat objective (UplanSApo; Olympus).²⁸ Statistical evaluation of FCCS results was carried out using OriginPro 2018 (64-bit) SR1 b9.5.1.195 (Academic) (OriginLab Corporation, Northampton, MA, USA).

Results and Discussion

Design of experiment (DoE) and Cytotoxicity

To get a basic understanding of gene delivery efficiencies for different formulations, we employed a design of experiment (DoE) approach to determine the transfection efficiency and the amount of expressed transgene. The DNA concentration, the lipid-to-DNA ratio, and the type of plasmid (minicircle DNA vs. parental plasmid DNA) were set as the factors. The influence of those factors on the two responses transfection efficiency (%GFP positive cells) and transgene expression (MFI) was investigated using the software MODDE. As transfection reagents, we used a formulation containing a cationic lipid (DOTAP), one formulation containing an ionizable lipid (DLin-MC3-DMA), and a commercial transfection reagent (Lipofectamine 3000). The results for DOTAP:chol showed that extruded DOTAP:chol nanoparticles were associated with higher transfection efficiencies and transgene expression levels than DOTAP:chol nanoparticles manufactured by microfluidics. Therefore, the extruded nanoparticles were used for the generation of DoE data. For DLin-MC3-DMA however, extrusion was not possible due to precipitation of the lipid nanoparticles during the extrusion process. This observation can be a consequence of the negative surface charge of polycarbonate membranes at pH 4 that leads to absorption of positively charged DLin-MC3-DMA to the membrane surface.²⁹ Therefore, for DLin-MC3-DMA the microfluidics approach was used to prepare the nanoparticles. The obtained data allowed for generation of a DoE model using the software MODDE v.9.0. The resulting models showed high R^2 and Q^2 values (see Table 1), which were higher than expected for transfection experiments. Values above 0.5 for both parameters are acceptable and indicative of high predictability. With two exceptions (the MFI model for Lipofectamine 3000 in Hep3B cells and the GFP model for Lipofectamine 3000 in HuH7 cells), all R^2 values were above 0.65 and all Q^2 values were above 0.5. This indicates that the models reflect the actual data well and that they possess a good prediction precision. The low model validity observed for DOTAP and DLin-MC3-DMA and the response median fluorescence intensity in HuH7 cells (Figure S5, Figure S11) can be explained by the high reproducibility, leading to the validity term turning to negative values.³⁰ The models for Lipofectamine 3000 were characterized by a generally lower R^2 and Q^2 values compared to the other transfection reagents.

Table 1: Multiple correlation coefficients (R^2) and cross-validated R^2 (Q^2) of the generated models. The table depicts the R^2 values («goodness of fit») and the Q^2 values («predictive ability of the model») for the models generated for each cell line and transfection reagent. All results for the different cell lines and transfection reagents were fitted using partial least squares projection (PLS). Generally, a Q^2 value close to the R^2 value is indicative of a good model. R^2 and Q^2 values should be >0.5 for a good model. All models were generated from $n=3$ independent experiments.

A representation of the resulting contour plots (in HuH7 cells) is shown in Figure 1. Using minicircle DNA, the highest transfection efficiencies were observed using DLin-MC3-DNA, followed by Lipofetamine 3000. This observation was consistent across all investigated cell lines (see Supporting Information Fig. S2 - Fig. S18). Nanoparticles based on DLin-MC3-DNA exhibited a remarkable efficiency in transfecting all investigated cell lines using minicircle DNA with almost 100% of the cells expressing GFP (at 2 $\mu\text{g}/\text{mL}$ DNA concentration). High efficiencies using this compound were already shown previously for siRNA and in a clinical setting.³¹⁻³⁴ In addition to that, our results demonstrate the usefulness of DLin-MC3-DNA-based nanoparticles for the delivery of small DNA moieties. However, despite the very high transfection efficiencies, the subsequent transgene expression was lower compared to Lipofetamine 3000 which showed the highest transgene expression levels (up to 22000 RFU) across all cell lines. Still, except for Hep3B cells, DLin-MC3-DNA showed higher transgene expression levels (up to 3000 RFU) than DOTAP:chol. Therefore, DLin-MC3-DNA can be regarded as efficient transfection reagent for small DNA molecules. When using the parental plasmid DNA, however, both the transfection efficiency and the transgene expression following DLin-MC3-DNA-mediated gene delivery dropped drastically. The larger parental plasmid DNA was not delivered successfully (up to 1.25% GFP positive cells) and did not elicit a marked gene expression (<300 RFU).

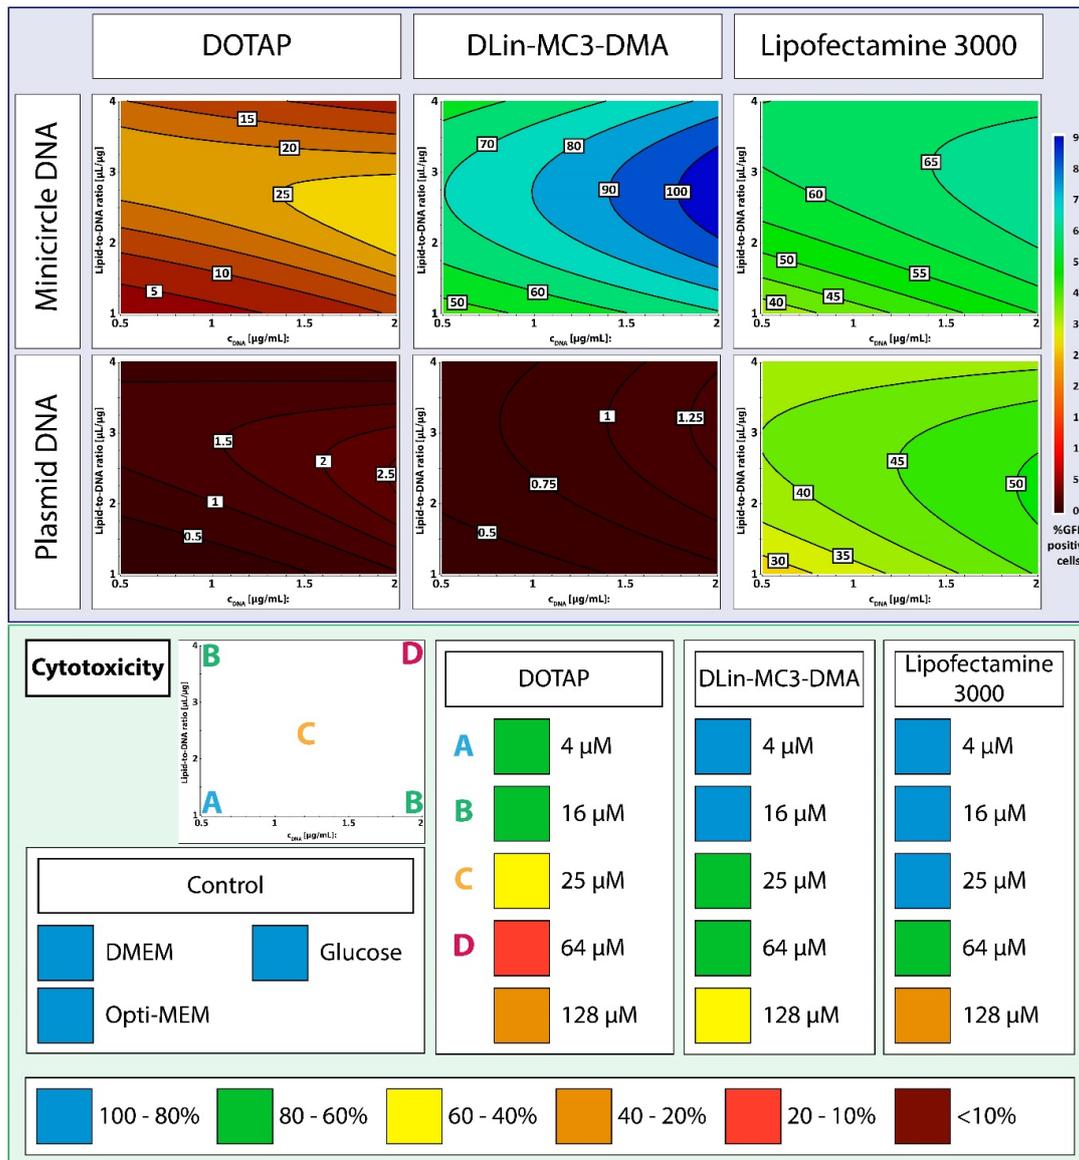

Figure 1: Comparison of the transfection efficiency of the employed nucleic acids and cytotoxicity of the applied transfection reagents in HuH7 cells. The figure displays the transfection efficiency of minicircle DNA (top row) and parental plasmid DNA (bottom row) as 2D contour plots generated by MODDE using the data of a design of experiment (DoE) in the blue box. With all employed transfection reagents, minicircle DNA is associated with markedly increased efficiency compared to parental plasmid DNA. The green box displays the cytotoxicity of the employed compounds. A concentration of 4 μM corresponds to the setting of 0.5 μg/mL DNA and a lipid-to-DNA ratio of 1 μL/μg while the highest amount of lipid applied at 2 μg/mL DNA and a lipid-to-DNA ratio of 4 μL/μg resulted in a final concentration of 64 μM. The highest level (128 μM) was not included in DoE runs but in cytotoxicity determination to better assess the cytotoxic potential of the used transfection reagents. The formulation containing DLin-MC3-DMA improved most following replacement of parental plasmid DNA. Lipofectamine was the least affected transfection reagent. Moreover, the DLin-MC3-DMA formulation showed the lowest cytotoxic potential of all employed transfection reagents. Data represented in the transfection box (blue box) is based on a model generated by MODDE using the data obtained during the DoE experiments (n = 3). The data in the cytotoxicity box (green box) is based on the average of six parallel measurements conducted in three independent experiments.

Consequently, DLin-MC3-DMA is highly sensitive to plasmid size. A possible explanation for this observation is the fact that DLin-MC3-DMA was optimized for delivery of siRNA leading to suboptimal interactions with large nucleic acids. A less distinct drop in efficiency was also observed for

DOTAP:Chol but not for Lipofectamine 3000. It is noteworthy that the transgene expression levels of Lipofectamine 3000 were far higher than those of DOTAP:cholesterol and DLin-MC3-DMA. Lipofectamine 3000 (except for in HepG2 cells) and DLin-MC3-DMA showed a marked influence of the dose of DNA with higher doses leading to higher percent transfected cells and transgene expression. The lipid-to-DNA ratio showed a less pronounced influence on the responses. In contrast to this, for DOTAP, a high lipid-to-DNA ratio is important for a high percentage of transfected cells, whereas a high dose of DNA is important for high transgene expression levels.

Besides transfection efficiency and transgene expression capabilities, nanoparticulate gene delivery systems also need to be well tolerated by cells and therefore, show a low cytotoxicity. A comparison between the cytotoxicity (determined by MTT assay) of nanoparticles and of nanoparticles complexed with DNA did not show significant differences. This suggests that the cytotoxicity depends on lipid moieties and cannot be attenuated by complexed DNA molecules. The cytotoxic potential of all three transfection reagents is shown in Figure 1. Both, DLin-MC3-DMA and Lipofectamine 3000 were well-tolerated up to lipid nanoparticle concentrations of 64 μM . It is noteworthy that this concentration was not exceeded in any experiment and the 128 μM data point was only included to extend the tested dose-range beyond the experimental range of the DoE. DOTAP:cholesterol nanoparticles were also well-tolerated up to a concentration of 16 μM but showed a distinct cytotoxic potential at higher concentrations. Especially in the setting employing a high dose of DNA in combination with a high lipid-to-DNA ratio, DOTAP:cholesterol shows a lower cellular survival than DLin-MC3-DMA, and Lipofectamine 3000.

DNA in lipid nanoparticles quantification

A possible explanation for the improved performance of minicircle DNA might be the number of plasmids delivered to cells. A rough calculation based on number of base pairs implies that 1 μg of minicircle DNA contains approximately 3.8 times more individual DNA molecules compared to parental plasmid DNA. If we perform experiments based on a $\mu\text{g}/\text{mL}$ DNA amount and add a fixed amount of lipid nanoparticles to our DNA sample, it would be tempting to assume that minicircle DNA-based lipoplexes led to higher transfection efficiencies simply due to the fact that there are more DNA molecules present compared to parental plasmid DNA-based lipoplexes.

To improve our understanding of the properties of nanoparticles derived from either minicircle DNA or parental plasmid DNA, fluorescence cross-correlation spectroscopy (FCCS) was applied. FCCS experiments were conducted on Cy5-labeled plasmid samples, Dil-labeled nanoparticle samples, and the lipoplexes obtained after combination of plasmids and nanoparticles. Each fluorescence correlation curve is the average of three measurements and curves are lifetime corrected. The resulting molecular brightness (count per molecule) levels were used to normalize the number of DNA molecules per nanoparticle. The results of the fluorescence lifetime measurements are shown in Table 1 and the autocorrelation curves (ACFs) of DNA molecules alone and nanoparticles alone are shown in Figure S19 and Figure S20. First, FCCS data suggests that the DNA samples are clean, *i.e.*, there is no extra phase from the free dye, which was true for parental plasmid DNA as well as minicircle DNA. According to calculations, pure minicircle DNA samples (1.4 kb) should have almost four-fold higher molarity than parental plasmid DNA (5.4 kb). However, our measurements revealed 1.9 nM and 0.9 nM concentrations for both plasmids, respectively. This discrepancy can be explained by two experimental shortcomings. First, recovery of DNA was incomplete after fluorescence labeling (155 $\mu\text{g}/\text{ml}$ and 393 $\mu\text{g}/\text{ml}$ recovered concentrations for minicircle DNA and plasmid DNA, respectively). Second, losses of DNA during complex formation leading to an additional loss of plasmid DNA but not minicircle DNA. Thus, final concentrations of DNA in the experiment were much

smaller than expected. This emphasizes the need to carefully monitor DNA concentrations at all stages of the experiment. It is tempting to speculate that DNA losses are caused by unspecific adsorption of DNA-containing lipoplexes to surfaces. Interestingly, both effects seem to depend on plasmid size and cannot readily be explained.

Due to the differences between calculated and experimental DNA concentrations in our experiments, we had to question our initial assumption of a uniform mode of interaction between DNA molecules of different size and lipoplexes. Indeed, Cy5 lifetime measurements revealed that lipoplexes using DOTAP and DLin-MC3-DMA show a prolongation of Cy5 τ_1 lifetimes. On the other hand, τ_2 is reduced, pointing to a larger exposure or to the sensing of the different chemical environments of DOTAP and DLin-MC3-DMA. The τ_1 and τ_2 shifts for Lipofectamine 3000 interactions are qualitatively and quantitatively different, with both values shifting to shorter lifetimes. This is indicative for a different mode of interaction with DNA.

Table 2: Results of the fluorescence lifetime measurement obtained by fluorescence correlation spectroscopy (FCS).

Sample:	Fluorophore:	τ_1 fluorescence lifetime [ns]:	τ_2 fluorescence lifetime [ns]:
Minicircle DNA	Cy5	0.842 ± 0.006	1.994 ± 0.006
Minicircle DNA/DOTAP	Cy5	0.922 ± 0.009	1.803 ± 0.007

Parental plasmid/DLin-MC3-DMA	Cy5	0.850 ± 0.010	1.707 ± 0.004
Parental plasmid/Lipofectamine 3000	Cy5	0.574 ± 0.005	1.404 ± 0.007
DOTAP	Dil	0.921 ± 0.011	1.650 ± 0.029
DOTAP/minicircle DNA	Dil	0.785 ± 0.009	1.416 ± 0.016
DOTAP/parental plasmid	Dil	0.780 ± 0.004	1.480 ± 0.011
DLin-MC3-DMA	Dil	0.856 ± 0.005	1.680 ± 0.013
DLin-MC3-DMA/minicircle DNA	Dil	0.792 ± 0.007	1.760 ± 0.013
DLin-MC3-DMA/parental plasmid	Dil	0.793 ± 0.005	1.806 ± 0.009
Lipofectamine 3000	Dil	0.705 ± 0.011	1.540 ± 0.043
Lipofectamine 3000/minicircle DNA	Dil	0.454 ± 0.008	1.410 ± 0.049
Lipofectamine 3000/parental plasmid	Dil	0.461 ± 0.007	1.390 ± 0.035

Lifetime measurements for Dil vary as well among the different formulations. The interaction of nanoparticles with DNA led to shifts in both measured lifetimes of Dil and are probably influenced by the change in the chemical potential in the surrounding of the nanoparticle and/or the rearrangements of molecules within the nanoparticle. In particular, shifts in τ_1 lifetimes towards shorter lifetimes suggests displacement of Dil by DNA. Shifts in the τ_2 lifetime are related to changes in chemical compositions and membrane rearrangement.

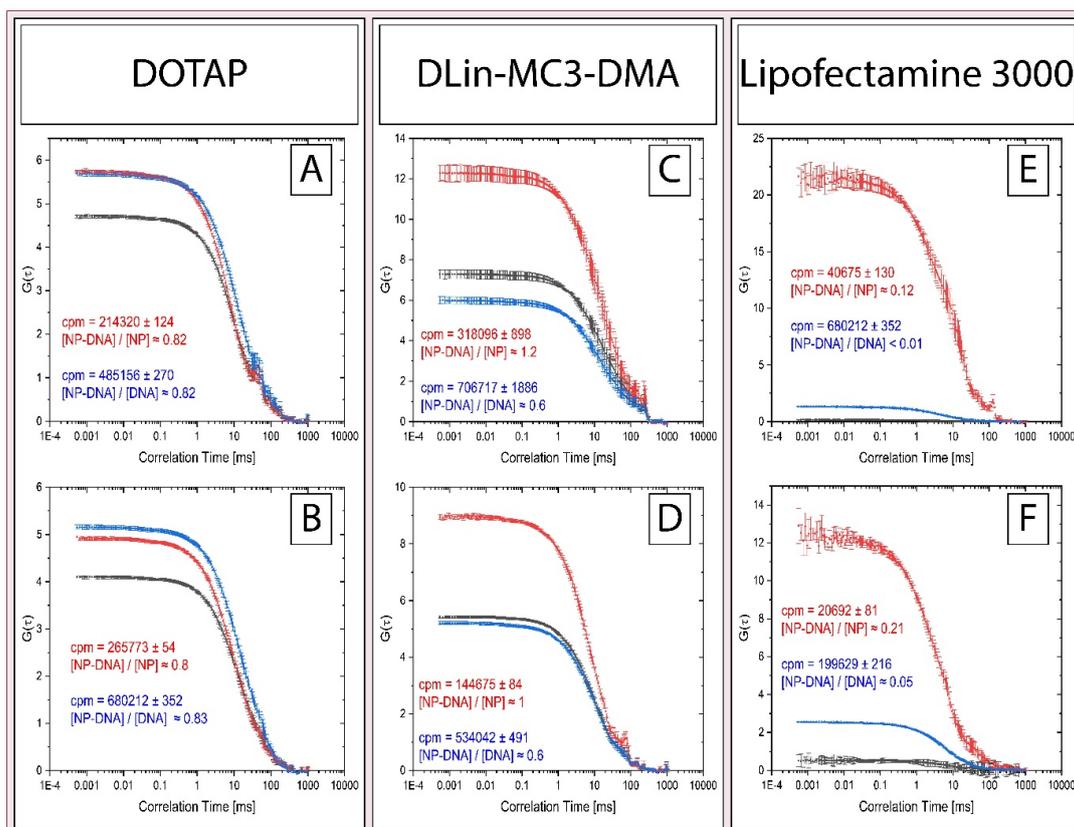

Figure 2: Autocorrelation functions (ACFs) for labeled DNA and nanoparticle samples following fluorescence cross-correlation spectroscopy (FCCS) measurements. The picture depicts the ACFs of DiI-labeled nanoparticles (red) and either Cy5-labeled mcDNA or Cy5-labeled ppDNA (blue) and the associated cross-correlation functions (black) obtained after FCCS measurements. The plots depict the results for the combination of DOTAP with either mcDNA (A) or ppDNA (B), DLin-MC3-DMA with either mcDNA (C) or ppDNA (D), and Lipofectamine 3000 with either mcDNA (E) or ppDNA (F). FCCS measurements for DOTAP indicate that at the given concentration, most (approx. 80%) of the nanoparticles are involved in interactions with DNA. DOTAP/DNA nanoparticles appear to be the most stable sample and the binding stoichiometry is approximately 2:1 (DNA:DOTAP) for both plasmid types. For DLin-MC3-DMA, basically all nanoparticles interact with DNA irrespective of the type of DNA and for both plasmid types, single DNA molecules interact with multiple nanoparticles. In contrast to this, DNA and Lipofectamine 3000 are mainly unbound, again irrespective of the type of DNA. The results indicate again for both types of plasmids that several DNA molecules interact with one nanoparticle. ($n=3$)

The results of the FCCS measurements are displayed in Figure 3 and allow us to calculate not only the fractions of bound and unbound particles (both nanoparticles and DNA molecules) but also the binding stoichiometry of the involved molecules. To our knowledge, these results are unique in that binding stoichiometries of nanoparticles for gene delivery were only calculated but not measured so far. The most stable nanoparticle/DNA interaction was found with DOTAP nanoparticles. The concentration ratio between bound partners and free species (*i.e.*, $[NP-DNA]/[NP]$, and $[NP-DNA]/[DNA]$) can be determined in a first approximation by $G_{Complex}(0)/G_{DNA}(0)$ and $G_{Complex}(0)/G_{NP}(0)$, respectively. We conclude that at the given concentration, approximately 80% of the DNA is involved in interactions with DOTAP nanoparticles. This observation in combination with the brightness levels indicate a binding stoichiometry of approximately 2:1 (DNA:DOTAP) for both plasmids. FCCS measurements for DLin-MC3-DMA revealed that basically all of MC3 is involved in the interaction with DNA. Similar amounts of minicircle DNA or parental plasmid interact with individual DLin-MC3-DMA nanoparticles. This together with the brightness levels suggests that a single DNA molecule interacts with multiple DLin-MC3-DMA nanoparticles with a stoichiometry of approximately 0.2:1 (DNA:DLin-MC3-DMA). However, the FCCS measurements also showed that large aggregates were

formed during the measurement of DLin-MC3-DMA-based nanoparticles. Surprisingly, FCCS measurements showed that DNA is not bound to Lipofectamine 3000. There is only a small difference in binding preference with respect to DNA size. This together with the brightness levels suggests that a single Lipofectamine 3000 nanoparticle interacts (albeit weakly) with multiple DNA molecules, irrespective of the type of DNA molecule. The binding stoichiometry for Lipofectamine 3000 was calculated to be around 6:1 (DNA:Lipofectamine 3000). We conclude that neither the binding stoichiometries, nor the extent of DNA binding correlate with transfection efficiency. These findings confirm microscopic observation (i.e. formation of large agglomerates), that Lipofectamine 3000 coprecipitates with DNA triggering unspecific uptake into target cells.

To determine the number of DNA molecules per nanoparticle, the brightness of individual samples (i.e., DNA molecules, nanoparticles) was normalized and compared to the brightness values of the mixtures (i.e., DNA/nanoparticle complexes). The results of these calculations are shown in Figure 3. First, the average number of plasmids in the confocal volume was determined for each combination of DNA and LNP (Number of Plasmids). For DOTAP and DLin-MC3-DMA, the number of minicircle DNA in the confocal volume was slightly higher compared to the number of parental plasmid DNA. This finding was expected, although to a larger extent, because the minicircle DNA preparation should contain more DNA molecules than its parental plasmid counterpart. Moreover, the average number of DNA molecules in the confocal volume was comparable for both preparations. However, we did not see a 4-fold difference in the number of DNA molecules in the confocal volume, which is in contrast to what calculations might suggest. For Lipofectamine 3000, the number of minicircle DNA was lower compared to the number of parental plasmid DNA (Figure 3). This finding is counterintuitive. There is a possibility that DNA/LF3000 complexes interact with or attach to surfaces, therefore being depleted during FCCS measurements. An indication for this hypothesis could be the lower number of nanoparticles in the confocal volume observed for Lipofectamine 3000 nanoparticles alone. In fact, Lipofectamine 3000-based nanoparticles often formed aggregates (see above). These aggregates will sediment faster than smaller nanoparticles and might therefore lead to sample depletion during the measurement. A similar pattern was observed for the average number of nanoparticles in the confocal volume (Number of Nanoparticles). The number of nanoparticles in the confocal volume was again higher for nanoparticles containing minicircle DNA than for nanoparticles containing parental plasmid DNA in DOTAP and DLin-MC3-DMA (Figure 4). However, the number of lipid nanoparticles in the confocal volume was approximately 10 times higher for DLin-MC3-DMA than for DOTAP, explaining the approximately tenfold difference in binding stoichiometries observed in FCS measurements. Here again, Lipofectamine 3000-based nanoparticles were associated with smaller numbers of nanoparticles when complexed with minicircle DNA as compared to parental plasmid DNA. These results confirm the initial approximations with respect to the binding stoichiometry.

We conclude from these experiments (Figure 4) that the number of plasmids per nanoparticle varies considerably between formulations: the number of plasmids per nanoparticle was approximately 2.7 for DOTAP, 0.19 for DLin-MC3-DMA, and 5.8 for Lipofectamine 3000. However, irrespective of DNA size, the same number of DNA molecules is bound to nanoparticles. Consequently, the higher efficiency of minicircle DNA cannot be attributed to a higher number of DNA molecules delivered to the cells but must be influenced by more favorable properties of minicircle DNA when it comes to transfection efficiency (e.g. cytoplasmic mobility,³⁵⁻³⁷ reduced epigenetic silencing due to a lack of bacterial backbone structures,³⁸⁻⁴⁰ or enhanced nuclear translocation^{41,42}). Indeed, Cy5-labeled minicircle DNA and Cy5-labeled parental plasmid DNA have different calculated hydrodynamic radii of approximately 55 nm and 100 nm, respectively (Supporting Information Figure S19). In line with this observation, Lukacs et al. showed that diffusion through the cytoplasm is highly restricted for larger DNA molecules compared with smaller ones.³⁷

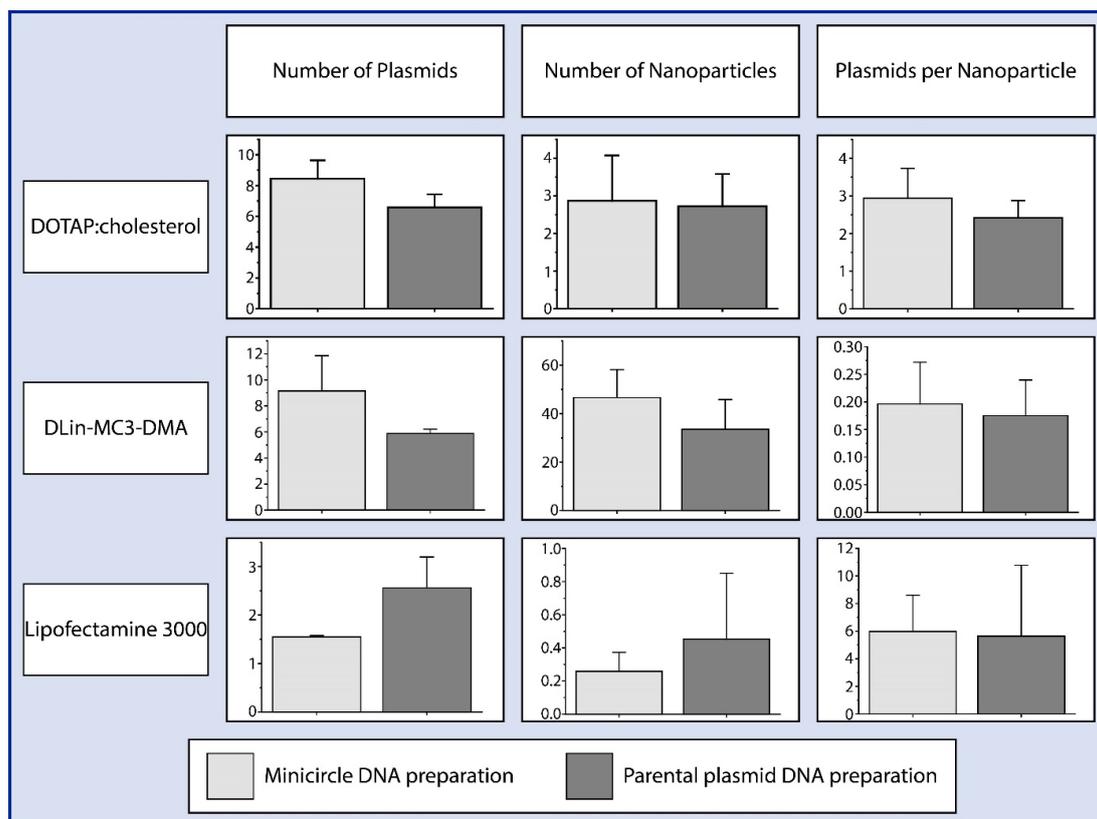

Figure 3: Quantification of plasmid molecules and nanoparticles in the confocal volume. The figure shows the number of plasmids and the number of nanoparticles in the confocal volume as well as the number of DNA molecules per nanoparticle. The panel on the left shows that the number of plasmids in the confocal volume is comparable following application of either minicircle DNA or parental plasmid DNA for DOTAP-based lipoplexes. Here are slightly more minicircle DNA molecules than parental plasmid DNA molecules in the confocal volume for DLin-MC3-DMA, while the opposite was observed for Lipofectamine 3000. The same observations as for DNA were also made for the number of nanoparticles in the confocal volume (middle panel). Therefore, the number of plasmids per nanoparticle is equal for preparations using minicircle DNA or parental plasmid DNA (right panel). Generally, the quantities were similar for the same formulation complexed with the two plasmids but differed largely between the three transfection reagents.

Results of the FCCS measurements allowed us to normalize the transfection efficiency and the transgene expression to the determined number of DNA molecules per volume unit (Figure 4). It is evident that normalization of experimental data is mandatory. This should be done using experimental data and not just calculated correction factors. Normalization based on calculated values is highly biased and would inevitably lead to misinterpretation of data. In particular, the superiority of minicircle DNA in combination with any transfection reagent could only be demonstrated using appropriate normalization procedures as recommended by this work.

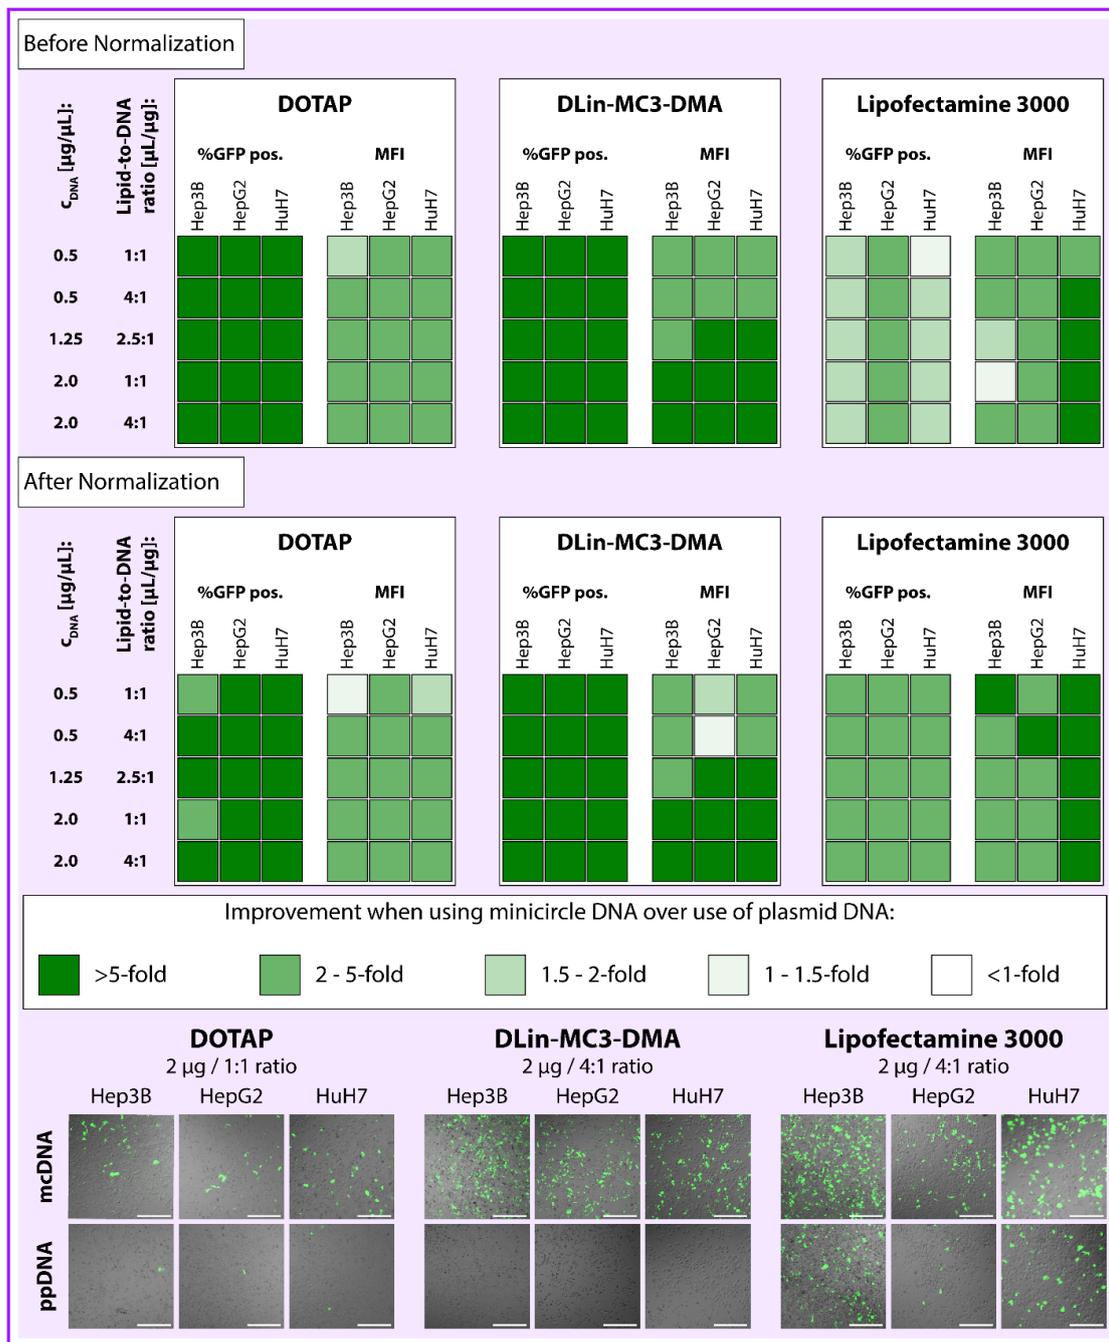

Figure 4: Improvement of transfection efficiency when using minicircle DNA instead of parental plasmid DNA before and after normalization to DNA concentration determined by FCCS. The figure shows the enhanced transfection efficiency following application of minicircle DNA compared to parental plasmid DNA for the three employed transfection reagents. The upper panel shows the improvement based on the results of the DoE, whereas the middle panel shows the improvement after normalization to the number of plasmids in the confocal volume determined by FCCS. Additionally, confocal images acquired at the settings of highest efficiency as determined by DoE are displayed for all three transfection reagents and both plasmids. Generally, the application of minicircle DNA improves transfection efficiency (%GFP positive cells) and transgene expression (mean fluorescence intensity, MFI) in all settings and with all transfection reagents by at least 1.4-fold. Both, DOTAP, and DLin-MC3-DMA profit most from the use of minicircle DNA with respect to transfection efficiency, and, in the case of DLin-MC3-DMA, also transgene expression.

Conclusion

Interactions between DNA molecules and nanoparticles seem to be more complex than anticipated. By applying FCCS we successfully implemented a fluorescence-based method to investigate such interactions. The results showed that assumptions based on calculations do not necessarily reflect the actual conditions. Furthermore, DNA/nanoparticle interactions are strongly dependent on the nanoparticle formulation whereas the size of the DNA molecule has only a minor influence. Consequently, comparisons between DNA molecules of different size, and especially between different formulations are not meaningful if these interactions are not determined for the applied formulations. Ideally such interactions are determined for each individual formulation because we could not identify a general trend that is true for all three formulations. Finally, in a comparison accounting for these observations, minicircle DNA in combination with different transfection reagents promotes higher transfection efficiencies and transgene expression levels compared to parental plasmid DNA when the number of delivered plasmids, and therefore also the number of delivered expression cassettes, is equal.

Acknowledgements

We thank Nicole Rimann of the University Children's Hospital Zurich for supply with minicircle DNA and corresponding parental plasmid DNA.

doi: 10.7554/eLife.42276.

Highlights: Nanoparticles with prolonged blood circulation time often do not accumulate in the target tissue to a sufficient amount. To increase accumulation in specific tissues or uptake into specific cell populations, a targeting strategy is needed. In this study, we demonstrate that modification of lipid-based nanoparticles with a targeting peptide derived from the hepatitis B virus large envelope protein (HBVpreS) enables specific uptake into hepatocytes *via* the sodium-taurocholate cotransporting polypeptide (NTCP). Selection of formulations with favorable pharmacokinetics and high targeting capacity was done using the zebrafish embryo animal model. Optimized formulations showed active NTCP-mediated targeting and cellular uptake into hepatocytes of mice confirming the hepatotropic nature of these targeted nanoparticles.

Optimization-by-design of hepatotropic lipid nanoparticles targeting the sodium-taurocholate cotransporting polypeptide

Abstract Active targeting and specific drug delivery to parenchymal liver cells is a promising strategy to treat various liver disorders. Here, we modified synthetic lipid-based nanoparticles with targeting peptides derived from the hepatitis B virus large envelope protein (HBVpreS) to specifically target the sodium-taurocholate cotransporting polypeptide (NTCP; *SLC10A1*) on the sinusoidal membrane of hepatocytes. Physicochemical properties of targeted nanoparticles were optimized and NTCP-specific, ligand-dependent binding and internalization was confirmed in vitro. The pharmacokinetics and targeting capacity of selected lead formulations was investigated in vivo using the emerging zebrafish screening model. Liposomal nanoparticles modified with 0.25 mol% of a short myristoylated HBV derived peptide, that is Myr-HBVpreS2-31, showed an optimal balance between systemic circulation, avoidance of blood clearance, and targeting capacity. Pronounced liver enrichment, active NTCP-mediated targeting of hepatocytes and efficient cellular internalization were confirmed in mice by ¹¹¹In gamma scintigraphy and fluorescence microscopy demonstrating the potential use of our hepatotropic, ligand-modified nanoparticles.

Introduction

The design of hepatotropic drug carriers is of great interest for the treatment of various liver disorders (Williams et al., 2014; Poelstra et al., 2012; Reddy and Couvreur, 2011). In particular if cell-type specific delivery of macromolecular therapeutic agents, selective targeting of parenchymal liver cells and internalization is needed. Previously, hepatocyte targeted nanoparticles have been developed exploiting endogenous and exogenous targeting ligand-based mechanisms using glycan, protein or antibody modifications of the nanoparticle surface (Akinc et al., 2010; Akinc et al., 2009; Barrett et al., 2014; Detampel et al., 2014; Witzigmann et al., 2016a). Most established systems for liver-specific drug delivery rely on targeting the hepatic asialoglycoprotein (ASGPR) or low density lipoprotein (LDLR) receptors. However, studies investigating alternative targeting strategies based on other hepatocyte-specific receptors are limited. In this respect, a promising alternative might be offered by the hepatitis B virus (HBV), which shows a pronounced efficacy to infect the human liver due to its strong affinity to hepatocytes. Less than 10 virus particles have been shown to

be sufficient to efficiently target hepatocytes of chimpanzees resulting in a pathogenic HBV infection (Asabe et al., 2009). The reason for its extraordinary liver tropism is a highly specific amino acid sequence in the large HBV envelope protein (i.e. HBVpreS1 domain), which is essential for target receptor recognition (Meier et al., 2013; Schieck et al., 2013). For decades, the specific target of HBV on the sinusoidal membrane of hepatocytes was unknown until in 2012 the interaction with the human sodium-taurocholate cotransporting polypeptide (NTCP/SLC10A1) was identified (Yan et al., 2012). Subsequently, Urban and colleagues performed a fine mapping of the HBVpreS sequence to identify the amino acids responsible for efficient binding (Schulze et al., 2010; Ni et al., 2014; Schieck et al., 2013). As a result, the first HBV/HDV entry inhibitor, a myristoylated peptide named Myrcludex B, was developed and successfully introduced in clinics (currently phase II clinical trials) (Blank et al., 2016; Urban et al., 2014). Myrcludex B binds with high affinity and specificity to human NTCP on the sinusoidal membrane of hepatocytes thereby blocking binding of virus particles to their target cells.

Based on these findings, the question arises whether Myrcludex B might serve as a targeting ligand to design a hepatotropic, NTCP-specific nanoparticle. In recent years, several groups have therefore attempted to develop targeting strategies based on HBV envelope proteins, for example recombinant HBV envelope protein particles (bio-nanocapsules) or HBV preS1-derived functionalized liposomes (Liu et al., 2016; Somiya et al., 2016; Somiya et al., 2015; Zhang et al., 2015; Zhang et al., 2014). However, the nanoparticulate drug delivery systems developed had physicochemical properties (e.g. size, colloidal stability, and immunogenic potential), which were sub-optimal for efficient in vivo targeting of hepatocytes. Especially the size of the nano-formulations presented a limitation. Most developed formulations had sizes above the average diameter of hepatic fenestrations in healthy humans (i.e. 100 nm) (Wisse et al., 2008) thereby limiting the passage through liver fenestrations and consequently the access to the space of Disse and the sinusoidal membrane of hepatocytes. Notably, the liver fenestrae diameter of rodents show high species and strain differences ranging from around 100 nm to 160 nm, possibly explaining positive liver targeting of published formulations (Braet and Wisse, 2002; Steffan et al., 1987; Wisse et al., 2008). In addition, a nanoparticle size above 100 nm triggers phagocytosis by cells of the reticuloendothelial system (i.e. hepatic Kupffer cells and spleen macrophages) resulting in rapid blood clearance (Kettiger et al., 2013). Both factors significantly decrease the likelihood of reaching the parenchymal liver tissue and increase the risk for potential off-target effects in untargeted tissues.

Surface properties are another important characteristic of nanoparticles. The surface charge (i.e. ζ potential) should be slightly negative (Xiao et al., 2011) to prevent sequestration of particles in the lung (i.e. due to a positive charge) (Ishiwata et al., 2000) or rapid clearance by cells expressing scavenger receptors (i.e. due to an excessive negative charge) (Rothkopf et al., 2005). According to the classical Derjaguin-Landau-Verwey-Overbeek (DLVO) theory of colloids, a neutral charge has to be avoided to prevent particle agglomeration. In addition to surface charge, steric stabilization by PEGylation mediates long circulating properties and prevents opsonization (Karmali and Simberg, 2011; Milla et al., 2012).

It was the aim of the present study to design and optimize a nanoparticle based on liposomes combined with derivatives of Myrcludex B to efficiently target hepatocytes while minimizing interactions with off-target cell types. Optimization of physicochemical properties of the nanoparticles included size and charge optimization and steric shielding by PEGylation. Derivatives of Myrcludex B were selected based on target binding, cellular uptake and their impact on the colloidal stability of nanoparticles. For the lipid membrane composition, we used a FDA and EMA approved multi-component lipid formulation based on Doxil (i.e. liposomal formulation of doxorubicin) (Barenholz, 2012). To design an optimal targeted system, several Myrcludex B derivatives with variations in the peptide sequence or fatty acid modification were covalently linked to the distal end of PEG-lipids. NTCP-specific and ligand-dependent uptake was confirmed in vitro using human liver-derived cell lines. Recently, Shan et al. reported huge discrepancies between in vitro systems and rodent experiments during the development of targeted nanomedicines (Shan et al., 2015). Therefore, we used the zebrafish as a complementary in vivo screening model based on our previous work (Sieber et al., 2019b; Campbell et al., 2018; Einfalt et al., 2018; Sieber et al., 2017). We assessed the effect of nanoparticles' ligand type and ligand density on their pharmacokinetics. To this end, human-derived cell lines lacking or expressing the human NTCP (hNTCP, SLC10A1) were xenotransplanted into zebrafish embryos prior to systemic administration of

nanoparticles. Finally, tissue distribution of dual-labeled nanoparticles was qualitatively (fluorescence-based) and quantitatively (radionuclide-based) investigated *in vivo* in mice to demonstrate the targeting potential of our hepatotropic nanoparticle platform in higher vertebrates.

Results and discussion

Design and characterization of a hepatotropic nanoparticle for NTCP-specific targeting

The aim of our study was the design of a hepatotropic, targeting ligand-modified nanoparticle. To this end, the surface of liposomal nanoparticles was modified using targeting peptides or lipopeptides derived from the preS1 domain of the HBV large envelope protein (**Figure 1A**). Based on a previous screening of 26 HBVpreS peptide variants, we selected Myrcludex B, the first HBV entry inhibitor (**Blank et al., 2016; Bogomolov et al., 2016**), and five additional Myrcludex B-derived peptides to evaluate the influence of amino acid sequence variations or acyl chain modifications on targeting efficiency and thereby optimize our hepatotropic nanoparticle. All Myrcludex B derived (lipo)peptides were synthesized in high yields and purity by standard solid phase peptide synthesis using Fmoc-chemistry (**Schieck et al., 2013; Schieck et al., 2010; Müller et al., 2013**). Lipopeptides were N-terminally modified with the fatty acids myristic acid (saturated C14) or capric acid (saturated C10), since our previous studies have shown that fatty acid modification is key for mediating interactions with target cells. C-termini of synthesized targeting (lipo)peptides were modified with cysteine residues to allow conjugation to the distal end of PEGylated phospholipids (DSPE-PEG2000-Maleimide) integrated into sterically stabilized liposomes. Coupling was achieved by a chemically reactive maleimide, giving rise to a metabolically stable thioether bond suitable for applications in living organisms (**Figure 1A**). Successful conjugation of Myrcludex B to lipid-based nanoparticles was demonstrated by fluorescence correlation spectroscopy using Myrcludex B-Atto488. The autocorrelation curve of nanoparticle conjugated peptides showed a significant shift to longer diffusion times as compared to the free peptide, with average diffusion times of $\tau_d = 1639 \mu\text{s}$ and $\tau_d = 192 \mu\text{s}$, respectively (**Figure 1—figure supplement 1**).

Liposome membrane partition coefficients of mono fatty acid modifications are orders of magnitudes lower as compared to di-lipid anchors. (**Sauer et al., 2006**) Therefore, the distearoyl anchor of DSPE results in a stable incorporation of the PEGylated phospholipid-targeting ligand conjugate in the lipid bilayer of liposomes (membrane partition coefficient $>10^3 \text{ mM}^{-1}$), whereas the PEG linker offers a flexibility to the distally tethered lipopeptides to extend away from the liposome surface. In addition, a thermodynamically favorable backward bending insertion of the acyl chain into the liposomal membrane is possible. A slight change in transition temperature evaluated by pressure perturbation calorimetry and differential scanning calorimetry confirmed this hypothesis (data not shown). The formulation yield of modified nanoparticles after purification was dependent on the conjugated Myrcludex B derived (lipo)peptide with $\text{preS2-48} > \text{Myr-preS2-31} > \text{Myr-preS2-48A} \geq \text{Myr-preS2-48} > \text{Cap-preS2-48}$.

Light scattering and electron microscopy verified that all nanoparticles, that Myrcludex B-derived peptide conjugated liposomes (modified without or with C14 acyl moiety) had a spherical morphology with a small size around 90 nm, narrow size distribution (*that is* PDI <0.2), and a slightly negative zeta potential (**Figure 1B, Table 1**). Only a small increase in the hydrodynamic size of about 2 nm was observed after conjugation of Myrcludex B-derived peptides (**Table 1**). The zeta potential of nanoparticles remained negative due to a negative net charge of Myrcludex B-derived lipopeptides at physiological pH. Thus, the physicochemical properties of nanoparticles were not significantly influenced by the surface modification with HBVpreS derived lipopeptides containing C14 acyl chains. Exceptions were nanoparticles modified with Cap-preS2-48, which had an average diameter of 134.28 nm and a PDI of 0.24 (**Figure 1B, Table 1**).

It is tempting to speculate, that the C10 acyl chain of Cap-preS2-48 interfered with liposome membrane stability. As compared to longer acyl chains the backward bending insertion of C10 acyl chains into intra-liposomal membranes is less stable, thus promoting faster dissociation and possible interactions with neighboring liposomes due to re-association with inter-liposomal membranes. This was also indicated by formation of aggregates resulting in shorter storage stability (data not shown). Previously published studies reporting a rapid partitioning of shorter lipid anchors from liposomal

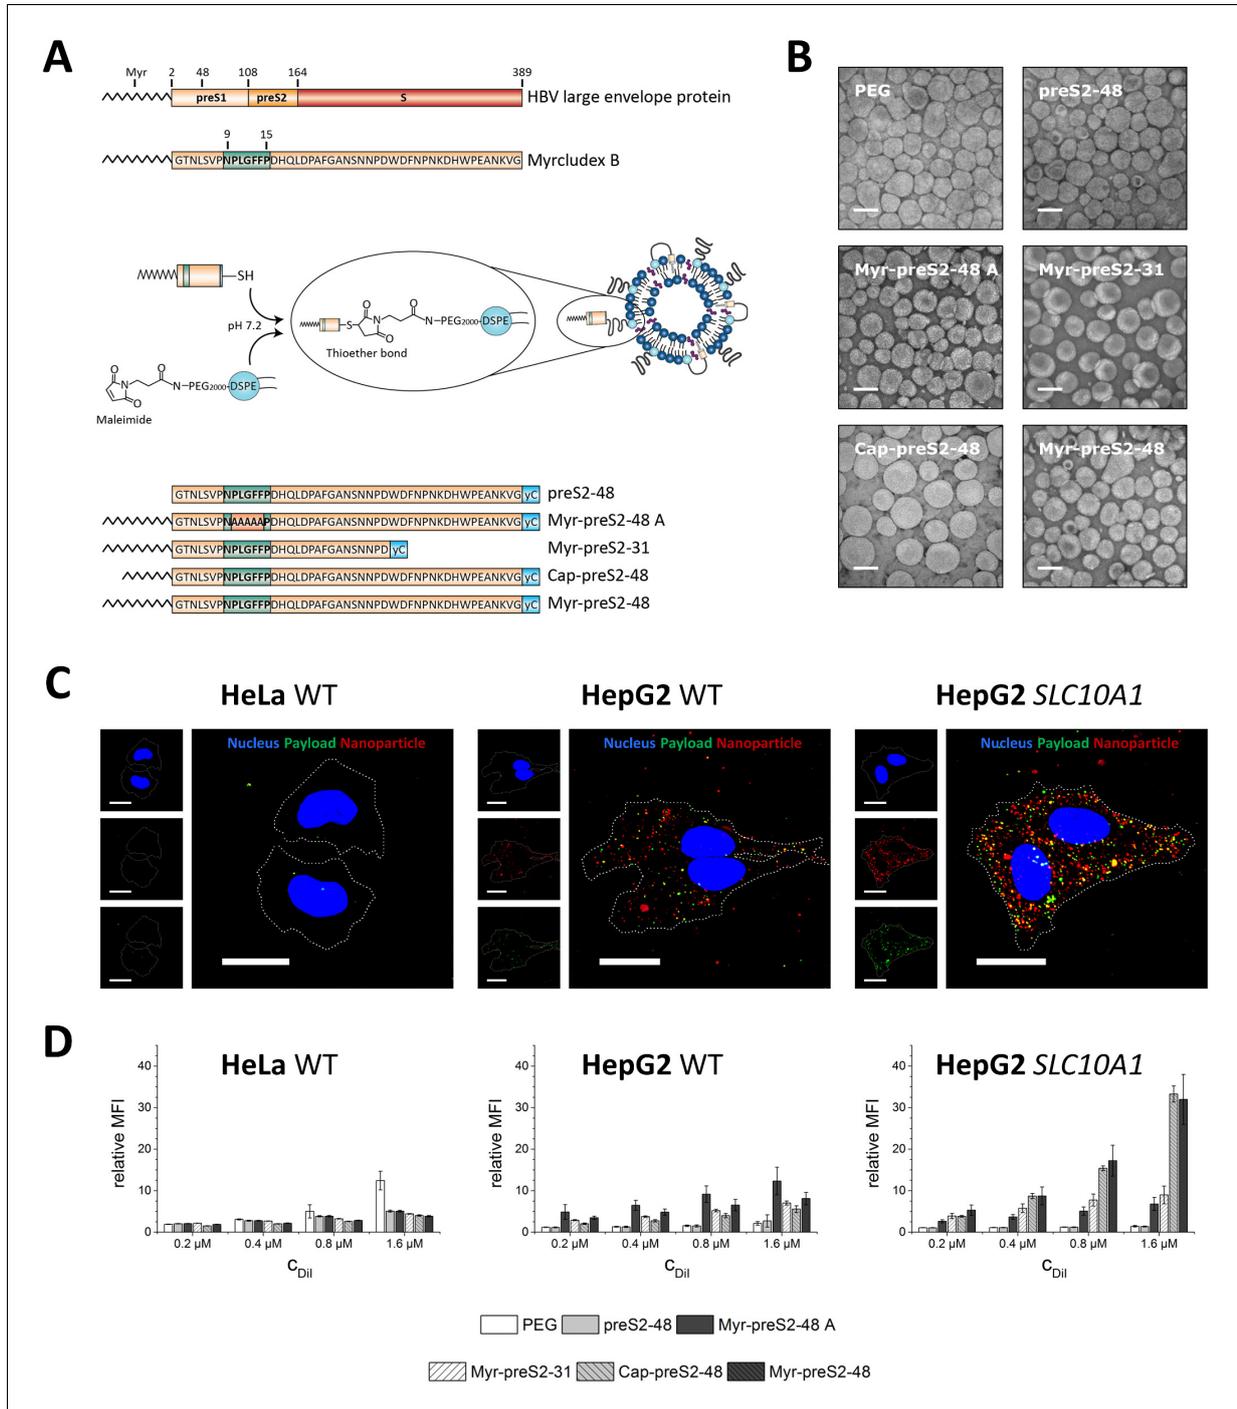

Figure 1. Hepatotropic nanoparticles based on liposomes modified with Myrcludex B-derived peptides for NTCP-specific targeting. (A) Schematic representation of peptides derived from Hepatitis B virus (HBV) large envelope protein including the first entry inhibitor, Myrcludex B. Different peptides were conjugated via thiol function to the distal end of PEG chains integrated in the nanoparticle structure using maleimide chemistry. vesicles support our observation of unfavorable liposome interactions for Cap-preS2-48 (Sauer et al., 2006; Webb et al., 1998).

Cellular uptake and viability

Next, we investigated the biocompatibility and targeting capacity of our ligand-modified nanoparticles in a panel of three different cell lines in vitro, that is non-hepatic HeLa cells devoid of *SLC10A1* (negative control), liver-derived wild type HepG2 cells (HepG2 WT, hepatocyte control cell line with no detectable *SLC10A1* expression based on PCR) and HepG2 cells overexpressing the human NTCP (HepG2 *SLC10A1*). We used lentiviral transduced cells overexpressing *SLC10A1* as a positive control to confirm the specificity of our system since human liver derived cell lines such as HepG2 and HuH7 down-regulated NTCP during oncogenic transformation (i.e. NTCP expression levels are significantly decreased in hepatocellular carcinoma) (Lempp et al., 2016). In all cell lines, nanoparticles showed a high cytocompatibility up to the highest tested lipid concentration of 8 mM, which is far beyond liposome blood concentrations achievable in a clinical setting (Figure 1—figure supplement 2 demonstrating no decrease of cell viability using the MTT assay) (Barpe et al., 2010).

In vitro uptake studies revealed that Myrcludex B-modified nanoparticles were rapidly internalized within 30 min into liver-derived HepG2 cell lines whereas no binding or cellular uptake was observed in non-hepatic HeLa cells (Figure 1C, representative confocal laser scanning microscopy images for Myr-preS2-48 modified nanoparticles). Both the liposomal nanoparticle (Dil signal) and the encapsulated payload (carboxyfluorescein (CF) signal), were detected intracellularly. Notably, CF was encapsulated into our nanoparticles at a fluorescence self-quenching concentration (i.e. 60 mM, Figure 1—figure supplement 3). Thus, CF fluorescence increases significantly after overcoming the Förster critical transfer distances, that is release of CF from nanoparticles into surrounding environment (Chen and Knutson, 1988). Specific uptake of nanoparticles with NTCP-binding component preS-peptide was enhanced with increasing *SLC10A1* expression levels (Figure 1C,D and Figure 1—figure supplement 4) demonstrating a high target specificity (i.e. HeLa WT < HepG2 *SLC10A1*). Surprisingly, the highest Dil signal (and not CF signal) in HeLa cells was observed with PEGylated nanoparticles. It is tempting to speculate that nanoparticle modification with Myrcludex B-derived lipopeptides decreases the interaction with negatively charged cell membranes of *SLC10A1*-deficient cells (e.g. HeLa) due to a negative net charge of lipopeptides at physiological pH and thus increased electrostatic repulsion. Uptake studies with a different liver-derived cell line (HuH7) comparing wild type and *SLC10A1* overexpressing cells confirmed the *SLC10A1* specific interaction. Overexpression of *SLC10A1* again resulted in a strong enrichment of cellular uptake ruling out an involvement of cell-line specific artifacts (Figure 1—figure supplement 5).

In order to demonstrate the potential application of Myr-preS2-31 modified nanoparticles as drug delivery system, we successfully incorporated small molecular payloads as well as larger compounds into nanoparticles payloads (i.e. propidium iodide, doxorubicin, FITC-labeled peptide, DNA vector) to enhance their internalization into NTCP expressing cells (Figure 1—figure supplements 6, 7, 8 and 9). Indeed, time-dependent uptake studies confirmed the rapid binding and internalization process of Myr-preS2-31 modified nanoparticles (Figure 1—figure supplements 6, 7 and 8). Of note, propidium iodide is a cell membrane impermeable drug. Thus, NTCP-targeted nanoparticles enabled internalization into cells and successful release into cytosol indicated by nuclear counterstain (Figure 1—figure supplement 7). To investigate the potential application of NTCP-targeted lipid nanoparticles as gene delivery systems, we encapsulated a DNA vector coding for GFP into lipid nanoparticles based on a clinically approved lipid composition and modified with Myr-preS2-31. High content screening analysis demonstrated that modification of nanoparticles with Myr-preS2-31 significantly increases the transfection of NTCP expressing cells (Figure 1—figure supplement 9). These experiments highlight future applications of the developed carriers and serve as a starting point for future extended in vivo studies in different species and disease models.

Competition of NTCP-specific cellular binding and uptake of targeting ligand-modified nanoparticles

To confirm specificity of NTCP interactions with Myrcludex B derived ligands, we used pre-incubations with free Myrcludex B-Atto565 to competitively inhibit nanoparticle binding and cellular uptake (Figure 2A). Fluorescently labeled Myrcludex B can be considered to be a suitable blocking agent

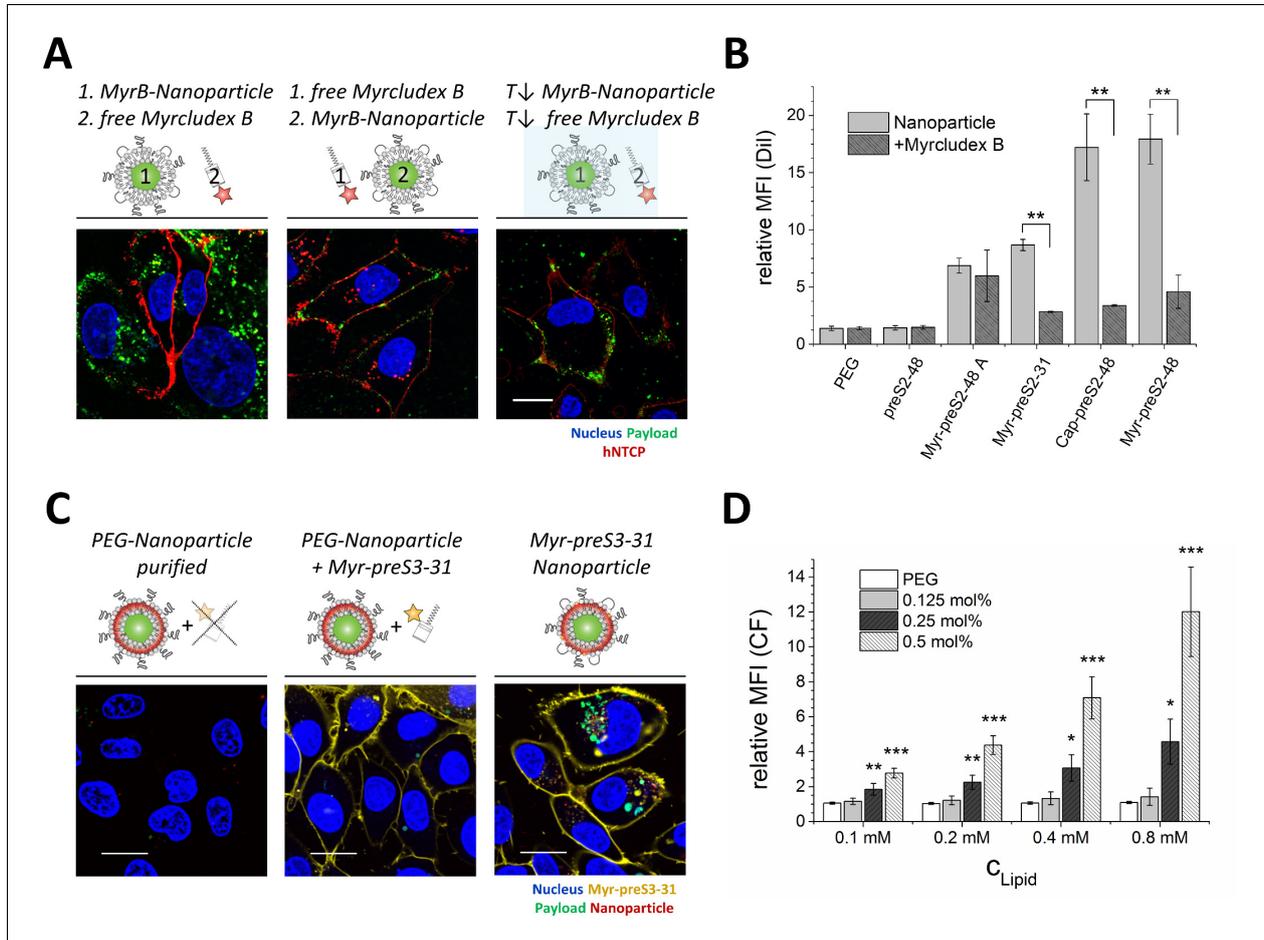

Figure 2. NTCP-specific and ligand-dependent uptake of Myrcludex B-derived lipopeptide conjugated nanoparticles into liver-derived cells in vitro. (A) Competitive inhibition study of Myrcludex B (MyrB)-conjugated nanoparticle uptake (carboxyfluorescein payload, green signal) into HepG2 *SLC10A1* already after 30 min. Free Atto-565 labeled Myrcludex B (red signal) was added after (left panel) or before (middle panel) nanoparticle. Uptake studies at lower temperature (T↓, 4°C, right panel) were performed to demonstrate energy-dependent process of nanoparticle internalization. Representative confocal laser scanning microscopy images are shown. Blue signal: Hoechst stain of cell nuclei. Scale bar = 10 μm. since its binding to NTCP expressing HepG2 *SLC10A1* cells results in a significant shift in fluorescence signal as compared to control cells (data not shown). Uptake inhibition of nanoparticles modified with Myr-preS2-31, Cap-preS2-48, and Myr-preS2-48 by free Myrcludex B-fluorescein was confirmed by flow cytometry (**Figure 2B**). In contrast, the uptake of Myr-preS2-48A modified nanoparticles was not significantly inhibited by free Myrcludex B, due to the non-specific amino acid sequence (see difference in essential amino acid sequence highlighted in **Figure 1A**). By incubation of cells in presence of NaN_3 or at low temperature (i.e. 4°C), we confirmed that the uptake of NTCP targeted nanoparticles is an energy-dependent process (**Figure 2A**). These results demonstrate that hepatotropism of nanoparticles is mediated by NTCP and that the cellular uptake of the carrier is an active and energy-dependent process.

Selection of the optimal hepatotropic Myrcludex B-derived lipopeptide

After evaluating the formulation yield, physicochemical characteristics (i.e. storage/colloidal stability, hydrodynamic diameter, size distribution, zeta potential) and the targeting capacity of our NTCP-specific nanoparticles in vitro, we identified Myr-preS2-48 and Myr-preS2-31 as lead structures and used these for further investigations. This choice was based on the following observations:

First, only nanoparticles modified with lipopeptides but not peptides without conjugated fatty acid (e.g. preS2-48) can bind to NTCP. This set of experiments confirmed that the acyl modification of peptides on nanoparticles' surface is a crucial prerequisite for hepatocyte binding as reported recently for free peptides (*Meier et al., 2013; Schieck et al., 2013*). Only acyl modified peptides increased nanoparticle binding and internalization. Second, liposomes decorated with peptides conjugated to capric acid had a reduced colloidal stability. Their storage stability was limited due to particle aggregation. Furthermore, their size of around 134 nm exceeds the diameter of liver sinusoid fenestrations presumably limiting their access to the space of Disse. Third, Myr-preS2-48A modified nanoparticles were excluded due to poor NTCP specificity as demonstrated by the lack of binding competition by free Myrcludex B. In addition, the uptake of these nanoparticles was independent of NTCP expression levels and even higher in HepG2 wild type cells (**Figure 1D**).

Mechanistic studies on NTCP mediated cellular binding and internalization

In order to demonstrate the importance of covalent peptide attachment, we used a triple fluorescence labeling strategy (**Figure 2C**). The targeting ligand Myrcludex B was labeled with Atto633, the liposomal phospholipid bilayer was labeled with Dil, and the aqueous cargo payload of nanoparticles consisted of CF. Myr-preS2-31-K-Atto633 was labeled at an additionally introduced lysine at position 2, in order to still allow conjugation to the nanoparticle surface by the terminal cysteine. Recently, we have shown that additional N-terminal amino acids do not interfere with specific liver enrichment (for comparison Myr-preS-11-48) (*Schieck et al., 2013*).

First, CF-loaded, Dil-labeled nanoparticles were incubated with Myr-preS2-31-K-Atto633 and purified using size exclusion chromatography to remove free targeting ligand. Cell experiments confirmed successful removal of free Myr-preS2-31-K-Atto633 (no signal on cell membrane) and as expected no uptake of PEGylated nanoparticles. As a control, we added a mixture of free Myr-preS2-31-K-Atto633 and PEGylated nanoparticles to HepG2 *SLC10A1* cells without prior purification. Notably, a strong fluorescence signal on the cell membrane was observed due to specific binding of free Myr-preS2-31-K-Atto633 to *SLC10A1* indicating specific targeting despite an additional N-terminal amino acid. Free Myr-preS2-31-K-Atto633 did not interact with PEGylated nanoparticles

and thus did not trigger nanoparticle entry into HepG2 *SLC10A1* cells. Finally, we covalently linked the Myr-preS2-31-K-Atto633 to the nanoparticle surface by Michael addition of the distal cysteine residue to maleimide-functionalized PEGylated phospholipids integrated in the nanoparticle structure. A strong cellular binding and uptake of Myr-preS2-31-K-Atto633 modified nanoparticles was observed already within 1 h.

Interestingly, nanoparticles including their payload entered the target cell whereas the targeting ligand remained on the cell surface. Since Myrcludex B has a remarkably high affinity to the Ntcp (K_D of 67 nM) (Meier et al., 2013), it is tempting to speculate that the targeting ligand is retained by Ntcp on the cell surface while the dissociated liposome payload is internalized and further processed by a yet unknown mechanism. Of note, intracellular CF signals were considerably higher when compared to Dil signals. This might also indicate liposome dissociation and perhaps loss of Dil during the internalization process. Uptake experiments using pharmacological pathway inhibitors suggested a partially clathrin-dependent and caveolin-independent mechanism, which differs from the process of phagocytosis and micropinocytosis (Figure 2—figure supplement 1). Intriguingly, additional factors besides Ntcp binding seem to contribute to this process. Non-hepatic HeLa cells transduced with mouse Ntcp (mNtcp; *Slc10a1*) or *SLC10A1* can bind Myrcludex B-modified nanoparticles. However, binding is reduced as compared to binding in hepatic cell lines and no uptake is observed (Figure 2—figure supplement 2). Thus, additional hepatic cell dependent factors seem to play a role for efficient binding and internalization. Indeed, Verrier et al. reported recently that glypican five expression is an important co-factor for HBV entry (Verrier et al., 2016). Notably, uptake experiments using psgA745 cells (CHO xylosyltransferase mutants) overexpressing Ntcp showed that binding of Myrcludex B alone is not influenced by glycosaminoglycans (Figure 2—figure supplement 3). In sharp contrast, binding of nanoparticles could be partially inhibited in HepG2 WT cells using heparan sulfate suggesting an involvement of glycosaminoglycans in the binding and subsequent internalization process of nanoparticles for hepatic cells (Figure 2—figure supplement 4). Therefore, it will be an important step for the design of next-generation carrier systems to elucidate such co-factors in detail and adapt the nano-sized delivery system accordingly.

To demonstrate concentration-dependent nanoparticle uptake of Myr-preS2-31 and investigate the effect of ligand density, qualitative and quantitative fluorescence techniques were used (Figure 2D). Therefore, we performed in vitro experiments using nanoparticles with variable amounts of coupled Myr-preS2-31 (0 mol% - 0.5 mol% initial maleimide functionalities on nanoparticle surface). With increasing targeting ligand concentration, a significant increase in cellular uptake was observed (Figure 2D, Figure 2—figure supplement 5). Notably, we identified a threshold value of at least 0.25 mol% for efficient cell binding by qualitative confocal imaging as well as quantitative flow cytometry experiments (Figure 2D, Figure 2—figure supplement 5). Below this value, no uptake was observed, whereas above 0.25 mol% cellular binding was improved. Stoichiometric estimations assuming a bilayer thickness of 5 nm, a phosphatidylcholine headgroup area of 0.71 nm² and an equal distribution of DSPE-PEG in the outer and inner nanoparticle membrane result in 157 ± 16 , 79 ± 8 , or 39 ± 4 maleimide moieties per liposome capable for lipopeptide conjugation corresponding to 0.5 mol%, 0.25 mol%, or 0.125 mol%, respectively (Maurer et al., 2001). Thus, a minimum of 80 functional maleimide moieties per nanoparticle is necessary for efficient cellular targeting after Myr-preS2-31 conjugation.

In vivo systemic circulation in the zebrafish vertebrate model

Since in vitro experimental models are not able to mimic the physiological complexity of nano-bio interactions at an organ level, we screened in the next step the effect of ligand density on pharmacokinetics of nanoparticles in vivo for Myr-preS2-48 and Myr-preS2-31 (Figure 3). Recently, we have reported that the zebrafish is a valuable pre-clinical tool to assess the systemic circulation and blood clearance of nanoparticulate drug delivery systems in vivo (Sieber et al., 2017; Campbell et al., 2018; Sieber et al., 2019b; Park, 2017; Yin et al., 2018; Sieber et al., 2019a).

Thus, we injected Dil labeled nanoparticles modified with different amounts of targeting ligand (0.125 mol% - 1.0 mol%) into the duct of Cuvier of transgenic *kdr:l:EGFPs843* zebrafish embryos which express GFP in the vasculature endothelial cells. Already 1 h post injection, a clear qualitative difference in circulation characteristics of tested nanoparticles was detected. With increasing ligand density on the nanoparticle surface, the systemic circulation of nanoparticles decreased for both peptides (Figure 3) indicating that ligand modification of nanoparticles interferes with the shielding

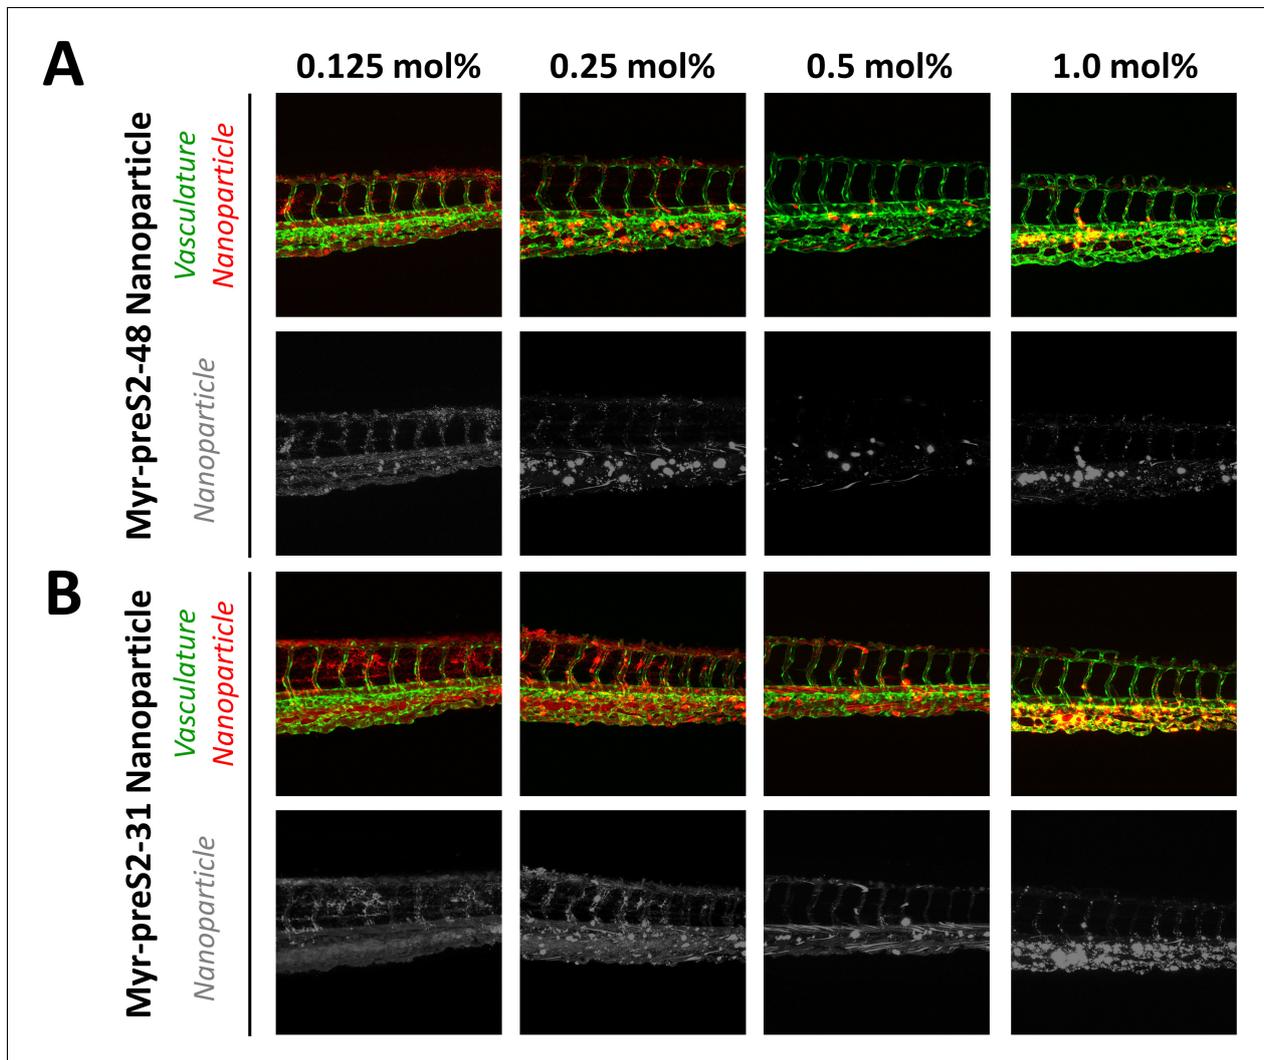

Figure 3. Systemic circulation of Myrcludex B-derived lipopeptide conjugated nanoparticles in vivo in the zebrafish model. Nanoparticles were modified with different amounts of (A) Myr-preS2-48 or (B) short Myr-preS2-31 and injected into transgenic zebrafish embryos expressing green fluorescent protein in their vasculature endothelial cells (green signal). Membrane of nanoparticles was fluorescently labeled using Dil (red signal). Representative confocal laser scanning microscopy images of tail region 1 hpost injection.

DOI: <https://doi.org/10.7554/eLife.42276.022>

properties of PEG. Increased blood clearance was thereby paralleled by accumulation in the posterior caudal vein region. The observed binding pattern did not match a *stabilin-2* scavenger receptor dependent nanoparticle clearance, which would be indicative for interactions with mammalian liver sinusoidal endothelial cells (LSECs) (Campbell *et al.*, 2018). More likely a sequestration by macrophages is responsible for this clearance mechanism corresponding to an accumulation in the spleen of rodents (Sieber *et al.*, 2019b).

Interestingly, nanoparticles modified with the shorter targeting peptide, that is Myr-preS2-31, showed increased systemic circulation (**Figure 3B**) as compared to Myr-preS2-48 modified nanoparticles (**Figure 3A**) at similar ligand densities. Thus, Myr-preS2-31 modified nanoparticles were selected for further investigations. However, nanoparticles modified with more than 0.5 mol% Myr-preS2-31 were as well excluded from further evaluation due to their poor systemic circulation and high clearance rate.

In vivo targeting ability in the zebrafish vertebrate model

In a next step, we investigated the targeting capacity of Myr-preS2-31 modified nanoparticles to human cells in vivo in the zebrafish model (**Figure 4**). In recent years, several groups have used xenografted zebrafish for various investigations including the assessment of nanoparticles (**Sieber et al.,**

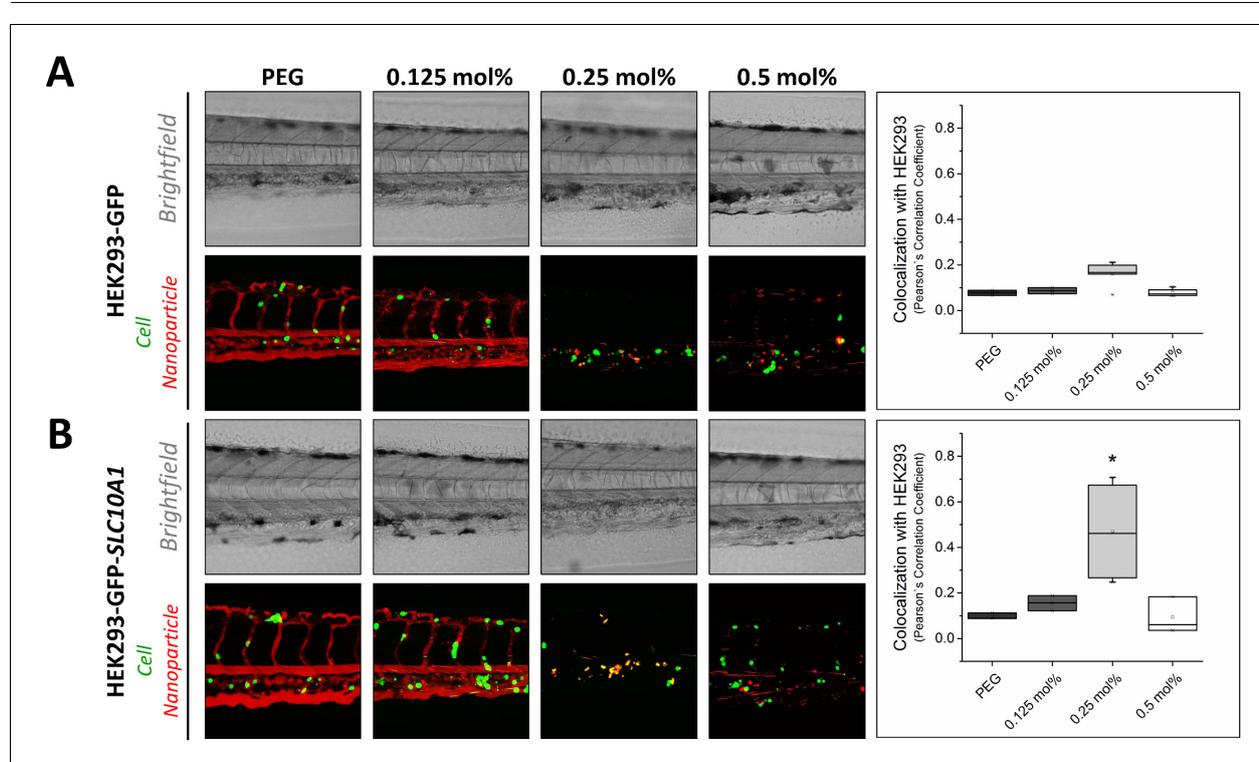

Figure 4. Targeting ability of Myr-preS2-31 conjugated nanoparticles in vivo in xenotransplanted zebrafish embryos. Nanoparticles were modified with different amounts of Myr-preS2-31 and injected into wild type zebrafish embryos xenotransplanted with human, GFP expressing HEK293 cells (green signal), (A) deficient or (B) expressing SLC10A1. Membrane of nanoparticles was fluorescently labeled using DiI (red signal). Yellow signals demonstrate colocalization (i.e. binding and internalization) of nanoparticles with HEK293-GFP cells. Representative brightfield and fluorescence images of tail region 1 h post injection are shown. Quantitative analysis of nanoparticle binding to HEK293-GFP cells is represented by Pearson's Correlation Coefficient (PCC). All values are shown as box plots of biological replicates ($n \geq 2$ independent experiments). * $p < 0.05$. Numerical data for all graphs are shown in **Figure 4—source data 1**.

Figure supplement 1. Targeting ability of free Myrcludex B in vivo in xenotransplanted zebrafish embryos.

DOI: <https://doi.org/10.7554/eLife.42276.024>

2019a; Evensen et al., 2016; Wertman et al., 2016; Brown et al., 2017; He et al., 2012; Lin et al., 2017; Veinotte et al., 2014; Wagner et al., 2010). Despite anatomical differences with mammals, zebrafish xenotransplantation models are an emerging preclinical tool offering several practical advantages as compared to mouse xenografting models including prolific reproduction, facilitated xenotransplantation (no immune rejection due to limited adaptive immune response), and optical transparency enabling high throughput screening. For our study, we used HEK293 cells stably expressing GFP for further genetic modification and establishment of xenotransplants (Witzigmann et al., 2015b). HEK293-GFP cells were transiently transfected with *SLC10A1* to express the targeting factor for our hepatotropic nanoparticles. Wild type HEK293-GFP without *SLC10A1* served as control. Both cell lines were injected into ABC/TU wild type zebrafish embryos to create human xenotransplants. The different nanoparticles were injected as soon as transgenic human cells stopped circulating and remained in the caudal vasculature tail region (i.e. after approximately 1 h). Interestingly, a clear difference in targeting capacity dependent on *SLC10A1* expression and ligand density was revealed. Whereas there was no significant difference in targeting capacity at different ligand densities for *SLC10A1*-deficient HEK293-GFP cells (Figure 4A), a significant increase in binding to HEK293-GFP cells was observed if *SLC10A1* was overexpressed as the nanoparticles could bind specifically and be readily internalized (Figure 4B). Most importantly, this was only valid for nanoparticles modified with 0.25 mol% Myr-preS2-31 (Figure 4, quantitative analysis). This illustrates that ligand density highly influences the balance between systemic circulation, systemic clearance rate and targeting efficiency of our liposome-based nanoparticles.

Nanoparticles modified with ligand densities below 0.25 mol% show a favorable systemic circulation but have an insufficient targeting ability. This also confirms our observations in vitro, where nanoparticles with a ligand density below 0.25 mol% did not significantly bind to HepG2 *SLC10A1* cells. In sharp contrast, nanoparticles modified with higher Myr-preS2-31 targeting ligand densities (i.e. 0.5 mol%) have increased targeting ability in vitro. However, decreased systemic circulation and a high clearance rate under in vivo conditions counteract the advantage of higher ligand densities. Nanoparticles modified with 0.25 mol% Myr-preS2-31 have the highest targeting efficiency due to an ideal balance between target affinity and long circulation time in vivo. It should be noted that nanoparticles are internalized by target cells (Figure 4B) whereas free Myrcludex B apparently binds with high affinity to target cells but is not internalized (Figure 4—figure supplement 1). This phenomenon was recently observed by our team in rodents (data not shown) and was also reported from clinical trials in humans.

In vivo liver targeting of Myr-preS2-31 conjugated nanoparticles in mice

To elucidate the influence of ligand density on hepatotropism of our nanoparticles in vivo in mammals, we evaluated the pharmacokinetic properties of Myr-preS2-31 conjugated nanoparticles in mice. For this set of experiments, we used a dual labeling approach. The radioactive nuclide indium-111 (^{111}In) was used for whole-body imaging and biodistribution studies whereas fluorescence labeling with Dil was used to evaluate intra-organ nanoparticle distribution. Importantly, we incorporated DTPA-conjugated DSPE into the lipid bilayer to chelate ^{111}In on the surface of nanoparticles. This radiolabeling strategy has distinct advantages as compared to other labeling techniques or loading of ^{111}In -oxine into nanoparticles (van der Geest et al., 2015). First, this radiolabeling method is robust, fast (within 45 min) and efficient with labeling efficiencies above 90%. Notably, free ^{111}In was easily removed from nanoparticle formulations prior to injection using size exclusion chromatography (NAP-5 columns). Second, DTPA-DSPE enables retention of ^{111}In in serum for at least 48 h at 37°C (>98% label retention) demonstrating the high stability necessary for in vivo studies of nanoparticulate drug delivery systems (van der Geest et al., 2015). Third, free ^{111}In is rapidly eliminated via kidneys and excreted in the urine as shown previously (Harrington et al., 2000; Shih et al., 2017). This offers an easy assessment to differentiate between non-bound and nanoparticle bound ^{111}In .

Four different lipid-based nanoparticles were prepared and injected intravenously into the tail vein of mice, that is PEGylated liposomes (negative control) and nanoparticles modified with 0.125 mol%, 0.25 mol% and 0.5 mol% Myr-preS2-31. Plasma and organs were harvested to perform a quantitative biodistribution analysis ex vivo 1 h post injection (Figure 5A). PEGylated nanoparticles showed the typical biodistribution of sterically stabilized nanoparticles with a strong signal in the blood (Figure 5A). Myr-preS2-31 conjugated liposomes demonstrated different biodistribution patterns depending on ligand density (Figure 5A). Modification of nanoparticles with 0.125 mol% Myr-

preS2-31 did not alter the systemic circulation significantly (*i.e.* high blood pool signal). Only a minor increase in liver accumulation was observed as compared to ligand-lacking PEGylated nanoparticles (**Figure 5A**).

Interestingly, nanoparticles modified with 0.25 mol% Myr-preS2-31 significantly enriched binding to the liver (**Figure 5A**). Further increase in ligand density (0.5 mol%) resulted in an increase in spleen accumulation, that is enhanced clearance by cells of the reticuloendothelial system (**Figure 5A**). Of note, none of the nanoparticle formulation resulted in an elimination via kidneys demonstrating the high stability and retention of the DTPA-DSPE chelated ^{111}In .

Planar gamma scintigraphy imaging of injected mice and harvested organs at various time points (15 min and 60 min) confirmed these observations (**Figure 5—figure supplements 1, 2 and 3**). PEGylated nanoparticles demonstrated the typical systemic circulation with a strong signal in highly perfused organs, for example heart (**Figure 5—figure supplements 1 and 2**). Modification of nanoparticles with 0.25 mol% Myr-preS2-31 significantly increased the liver accumulation. Interestingly, further increase in Myr-preS2-31 modification (≥ 0.25 mol%) resulted in dominant location of radioactivity in an elongated structure in the far-left part of the abdomen under the liver, which was identified as the spleen (**Figure 5—figure supplement 1**). In order to confirm this observation, we injected mice with excessive Myr-preS2-31 modified nanoparticles (>0.5 mol%) and performed a planar imaging (**Figure 5—figure supplement 3**). Indeed, elevated Myr-preS2-31 modification resulted in an exclusive spleen accumulation, that is enhanced clearance by cells of the reticuloendothelial system. In order to exclude species specific effects, we also performed a planar gamma scintigraphy imaging of harvested organs from injected rats (**Figure 5—figure supplement 4**). Again, elevated Myr-preS2-31 modification has negative impacts on liver accumulation.

In order to highlight the ligand-density dependent hepatotropism, we calculated ratios between the blood pool and important organs, that is liver (*i.e.* target organ), spleen (*i.e.* clearance organ), and kidney (*i.e.* control organ since nanoparticle bound ^{111}In should not show renal excretion) (**Figure 5—figure supplement 5**). Indeed, Myr-preS2-31 modification ≥ 0.25 mol% resulted in increased liver/spleen-to-blood ratios. Strikingly, nanoparticles modified with 0.25 mol% Myr-preS2-31 demonstrated a significant increase in the liver-to-kidney ratio confirming our conclusions from the zebrafish model, that 0.25 mol% Myr-preS2-31 is the optimal ligand density (**Figure 4B**).

The biodistribution studies were combined with fluorescence imaging of nanoparticle distribution (**Figure 5B**, **Figure 5—figure supplement 6**) and immunohistochemistry of Myr-preS2-31 distribution (**Figure 5C**, **Figure 5—figure supplements 6–9**) in liver, spleen, and kidney (*i.e.* nanoparticles and Myr-preS2-31 should not show renal excretion). PEGylated nanoparticles showed a weak fluorescent signal in the liver (**Figure 5B**). Importantly, these signals were not associated with the sinusoidal membrane of hepatocytes but arose from the high hepatic blood supply (**Figure 5—figure supplement 8**). No signals were observed in spleen and kidney (**Figure 5—figure supplement 6**). Modification of nanoparticles with 0.125 mol% Myr-preS2-31 did not result in significantly increased liver levels. A marginal binding of nanoparticles to hepatocyte membrane was visually observed (**Figure 5B,C**). This supports our hypothesis that a threshold level of targeting ligand density present on the nanoparticle surface is necessary for successful targeting. Importantly, strong signals for nanoparticles modified with 0.25 mol% Myr-preS2-31 were observed on the basolateral membrane of parenchymal liver cells (**Figure 5B,C**) demonstrating the strong hepatotropism of our nanoparticles. Further increasing the ligand density (*i.e.* 0.5 mol%) was detrimental and resulted in a diffuse hepatic staining pattern. Nanoparticles and their payload were detected as punctuated signals in the whole liver and did not show a specific membrane staining (**Figure 5B**, **Figure 5—figure supplement 9**). Myr-preS2-31 was detected in distinct localized areas only (**Figure 5C**). We conclude that nanoparticles modified with excessive Myr-preS2-31 densities (0.5 mol%) are rapidly cleared by liver resident macrophages, *i.e.* Kupffer cells. Subsequent re-distribution phenomena result in an unspecific nanoparticle signal in the whole liver.

Competition of NTCP-specific uptake into mouse hepatocytes in vivo

Since nanoparticles modified with 0.25 mol% Myr-preS2-31 allowed highly efficient liver targeting, we next investigated the NTCP specificity and the internalization process (**Figure 6A**). Therefore, we injected either labeled nanoparticles alone or together with free unlabeled Myrcludex B into mice (**Figure 6B**). Co-injection of Myrcludex B resulted in a clear decrease in liver enrichment by competitive inhibition of NTCP-binding as demonstrated by a change of signal.

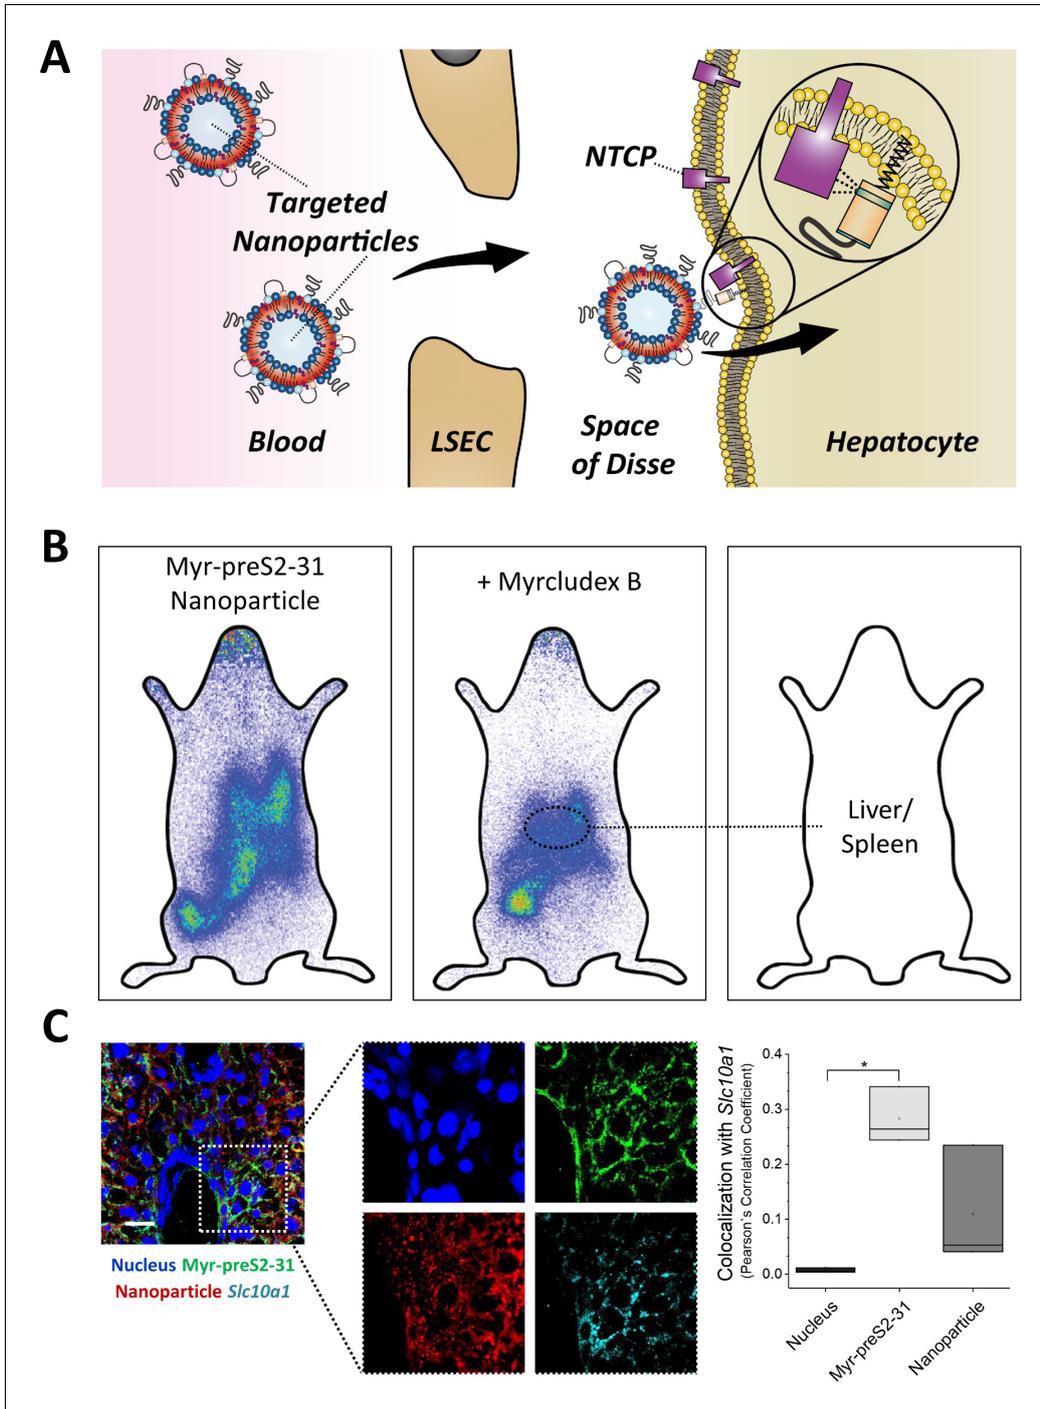

Figure 6. NTCP-specific uptake of Myr-preS2-31 conjugated nanoparticles into hepatocytes in vivo in mice. **(A)** Schematic representation of NTCP-targeted nanoparticle binding to hepatocytes. Circulating nanoparticles pass the fenestrae of liver sinusoidal endothelial cells (LSEC) and subsequently bind to the NTCP in the basolateral membrane of hepatocytes facing the space of Disse. Prior to Myr-preS2-31 mediated NTCP binding, the myristoyl chain is inserted into the lipid bilayer. In close proximity to hepatocytes, acyl chain switches into cellular membrane due to high affinity of essential

peptide sequence to NTCP binding site, thereby consolidating target transporter binding. (B) Nanoparticles were modified with 0.25 mol% of Myr-preS2-31 and labeled with radioactive ^{111}In and fluorescent membrane dye (DiI, red signal). Planar imaging of mice 1 h post-injection. Competitive inhibition of liver binding by co-injection of free Myrcludex B clearly demonstrates NTCP-specific binding. Positions of liver and spleen are indicated by small circles. (C) Immunofluorescence staining of nanoparticles (red signal), targeting ligand (Myr-preS2-31, green signal, antibody staining), and *Slc10a1* (cyan signal, antibody staining) in liver cryosections. Nuclei staining (blue signal) served as control for complete internalization; no overlap with *Slc10a1*. Scale bar = 20 μm . Colocalization analysis with *Slc10a1* is represented by Pearson's Correlation Coefficient (PCC). All values are shown as box plots of biological replicates ($n = 3$ independent experiments). * $p < 0.05$. Numerical data for all graphs are shown in **Figure 6—source data 1**.

DOI: <https://doi.org/10.7554/eLife.42276.037>

The following source data is available for figure 6:

Source data 1. Internalization into hepatocytes.

DOI: <https://doi.org/10.7554/eLife.42276.038>

To reveal the localization of nanoparticles, we performed a confocal microscopy analysis of liver cryo-sections (**Figure 6C**). We stained liver cryo-sections using antibodies against *Slc10a1* and Myr-preS2-31 (MA 18/7). Interestingly, nanoparticles that were internalized into parenchymal liver cells did not co-localize with *Slc10a1* fluorescent signals. Myr-preS2-31 still colocalized with *Slc10a1* suggesting that the targeting ligand was separated from the nanoparticle during cellular internalization as already observed in in vitro experiments. This phenomenon was confirmed by a colocalization analysis (**Figure 6C**). The observed cellular uptake is a surprising finding since HBV possesses pronounced host species specificity with regard to binding and infectivity. HBV binds to murine hepatocytes but cannot infect mice due to the lack of host cell dependency factors (**Lempp et al., 2016**). Therefore, chimeric mice transplanted with primary human hepatocytes have been developed to study anti-HBV drugs (**Petersen et al., 2008; Lütgehetmann et al., 2012**). In humans or chimpanzees only, HBV specifically binds to hepatocytes and subsequently infects the host.

Importantly, our NTCP-targeted nanoparticles apparently lack this species specificity. In contrast to HBV, our hepatotropic nanoparticles specifically bind to mouse hepatocytes in a *Slc10a1*-dependent manner and are subsequently internalized. The exact molecular interactions behind this internalization process will require additional studies to elucidate structural determinants important for cellular uptake and to better understand viral entry mechanisms, which are still unknown (**Glebe and Urban, 2007**).

Conclusions

In conclusion, the combination of in vitro investigations, the zebrafish model and in vivo experiments in rodents offered a unique approach to optimize our targeting ligand modified nanoparticles. The zebrafish model demonstrated to be an excellent tool to pre-screen various nanoparticle formulations, to assess the effect of Myrcludex B modifications on their pharmacokinetics and biodistribution, and thus increase the accuracy of predictions for experiments in rodents. The developed delivery systems can increase liver uptake levels, decrease accumulation in off-target tissues and at the same time avoid clearance by the reticuloendothelial system by mimicking HBV targeting properties. Despite the fact that current liver targeting strategies such as ASGPR- or LDLR-targeted delivery systems have already demonstrated improved drug and gene delivery in various preclinical models, these systems also suffer from certain drawbacks including complex synthesis of multivalent glycans or strong evidence that a majority of endocytosed gene carriers is recycled back to the cell exterior thereby reducing activity (**Witzigmann et al., 2016a; Sahay et al., 2013**). Due to the availability of efficient peptide manufacturing protocols, the proposed NTCP targeted delivery platform is an alternative and promising approach which warrants further investigation. For future clinical applications, optimized Myr-preS2-31 conjugated nanoparticles entrapping small molecule drugs, nucleic acids or proteins need to be studied in appropriate animal models of disease. In particular, we see a great potential for our nanoparticle targeting strategy in the field of metabolic diseases of the liver.

Synthesis of Myrcludex B-derived peptides

Different peptides were synthesized by fluorenylmethoxycarbonyl/t-butyl (Fmoc/tBu) solid-phase synthesis using an Applied Biosystems 433A peptide synthesizer and modified with acyl chains as described previously (Schieck *et al.*, 2013). Atto fluorescence dyes were either linked to the distal cysteine residue by maleimide chemistry or to the ϵ -amino group of an additionally introduced D-lysine at position two by NHS chemistry for mechanistic studies based on a triple fluorescence labeling strategy. In contrast to all other amino acids of Myrcludex B-derived lipopeptides, a D-amino acid was introduced in the latter case due to the chemical synthesis strategy used. Peptides were purified using preparative reverse-phase high performance liquid chromatography (HPLC, LaPrep P110, VWR International GmbH) with a Reprosil-Gold 120 C18 4 μ m column (Dr. Maisch GmbH) and a variable gradient adapted to the peptides properties in a range of 100% H₂O to 100% acetonitrile, both containing 0.1% TFA. Peptide identity was verified using an analytical Agilent 1100 HPLC system equipped with a Chromolith Performance RP-C18e column (Merck KGaA) coupled to a mass spectrometer (Exactive, Thermo Fisher Scientific).

Preparation of hepatotropic nanoparticles

Hepatotropic nanoparticles based on liposomes were prepared using the film rehydration extrusion method as described previously (Detampel *et al.*, 2014). The lipid membrane composition of nanoparticles consisted of DSPC (Lipoid AG), cholesterol (Sigma-Aldrich), DSPE-PEG2000 (Lipoid AG) at a molar ratio of 52.7:42.3:5. For the conjugation of HBV-derived peptides, DSPE-PEG2000 was replaced by DSPE-PEG2000-maleimide (Avanti Polar Lipids) at indicated molar ratios. For fluorescence labeling of lipid membrane, 1 mol% Dil (Thermo Fisher Scientific) was added to the lipid composition replacing DSPC. For radioactive labeling with ^{111}In , DSPC was replaced by 3 mol% DSPE-DTPA (Avanti Polar Lipids). Desired ratios of lipids were mixed; a homogenous thin film was prepared and dried using a Rotavapor A-134 (Büchi). Lipid films were rehydrated using 0.01 M PBS pH 7.2 containing 1 mM EDTA (Sigma-Aldrich) to prevent metal ion catalyzed maleimide oxidation. For passive loading and fluorescence labeling of inner core, a 60 mM 5 (6)-carboxyfluorescein (Sigma-Aldrich) solution (pH 7.4) was used for the rehydration step. At this concentration >98% of the fluorescence is self-quenched (Figure 1—figure supplement 3). Resulting multilamellar vesicles were subjected to five freeze-thaw cycles and extruded 11 times through a polycarbonate membrane (Avanti Polar Lipids) with a pore size of 100 nm followed by 11 times through a polycarbonate membrane with a 50 nm pore size 10°C above transition temperature (i.e. 65°C for DSPC-based formulations). For functionalization with HBV-derived peptides, nanoparticles were mixed with peptides at molar maleimide-to-cysteine ratio of 1:1 and incubated at RT overnight. To remove non-conjugated peptides and/or free hydrophilic dye, size exclusion chromatography using a Sephadex G50 column (GE Healthcare) eluted with 0.01 M PBS pH 7.4 was performed. The size exclusion chromatography column was coupled to an UV detector to analyze recovery of nanoparticles based on peak areas. Hepatotropic nanoparticles were concentrated to a final lipid concentration of 10 mM using Amicon Ultra-4 centrifugal filter units with a 100 kDa molecular weight cut-off (Millipore). Dil and cholesterol were used as marker lipids to quantify total lipid content. Dil content was quantified based on relative fluorescence signals as compared to liposome standards and in combination with Triton X-100 treatment to account for potential Dil self-quenching. Samples were excited at 561 nm and fluorescence signals were recorded using a Spectramax M2 microplate reader (Molecular Devices). The cholesterol content was determined using the Cholesterol E cholesterol assay kit from Wako following the manufacturer's protocol.

Loading of compounds into hepatotropic nanoparticles

FITC-peptide loading

For passive loading of FITC-Ahx-yKKEEEK into nanoparticles, a 2 mg/mL FITC-peptide solution in a mixture of PBS/DMSO/EtOH at pH 7.0 was used for the rehydration step of the homogenous lipid film. Resulting multilamellar vesicles were processed as described in the Materials and methods section.

Propidium iodide loading

For passive loading of propidium iodide into nanoparticles, a 10 mg/mL propidium iodide solution in PBS was used for the rehydration step of the homogenous lipid film. Resulting multilamellar vesicles were processed as described in the Materials and methods section including a final purification step.

Doxorubicin loading

For loading of doxorubicin, an active drug loading strategy based on a citrate gradient was used as previously described (Mayer *et al.*, 1990). The homogenous lipid film was rehydrated using a 300 mM citrate buffer at pH 4.0 and multilamellar vesicles were processed as described in the Materials and methods section. The pH of the external buffer solution was adjusted to pH 7.0 and nanoparticles were incubated with 2 mg/mL doxorubicin at 65°C for 15 min. Free doxorubicin was removed by size exclusion chromatography.

DNA vector loading

Lipid nanoparticles entrapping DNA were prepared as previously described with modifications (Kulkarni *et al.*, 2019; Kulkarni *et al.*, 2018; Kulkarni *et al.*, 2017). Briefly, lipids

(ionizable lipid, cholesterol, DSPC, DSPE-PEG2000, and DSPE-PEG2000-Maleimide at a molar ratio of 50:39:10:0.75:0.25 mol%) were dissolved in ethanol at a total lipid concentration of 15 mM. The DNA vector was dissolved in 25 mM sodium acetate (pH 4.0) at an N/P ratio of 6. After T-junction mixing at a flow rate ratio of 3:1 v/v, the pH was neutralized using a 5x excess of D-PBS, the appropriate amount of Myr-preS2-31 was added, and the resulting suspension was dialyzed against D-PBS to remove residual ethanol.

Physicochemical characterization of hepatotropic nanoparticles

Dynamic light scattering

Size and size distribution (polydispersity index, PDI) of nanoparticles were analyzed using a Delsa Nano C Particle Analyzer (Beckman Coulter) equipped with a 658 nm laser. Samples were measured in D-PBS at RT and a measurement angle of 165°. Data were converted using the CONTIN particle size distribution analysis (Delsa Nano V3.73/2.30, Beckman Coulter Inc).

Electrophoretic light scattering

Zeta potential of nanoparticles was analyzed using a Delsa Nano C Particle Analyzer. Samples were measured in D-PBS at RT and a measurement angle of 15°. Data were converted using the Smoluchowski equation (Delsa Nano V3.73/2.30).

Transmission electron microscopy

Size and morphology of nanoparticles were analyzed using transmission electron microscopy (TEM) as described previously (Witzigmann *et al.*, 2015a). In brief, samples were deposited on a 400-mesh carbon-coated copper grid, negatively stained with 2% uranylacetate, and analyzed using a CM-100 electron microscope operating at 80 kV (Philips).

Fluorescence correlation spectroscopy

Fluorescence correlation spectroscopy (FCS) analysis of nanoparticles was performed as described previously (Uhl *et al.*, 2017). In brief, Atto488, Myr-preS2-48-Atto488 and Myr-preS2-48-Atto488 conjugated nanoparticles were analyzed using an inverted confocal fluorescence laser scanning microscope (Zeiss LSM 510-META/Confocor 2) equipped with a 40 × water immersion objective lens (Zeiss C-Apochromat 40×, numerical aperture 1.2). Fluorescence intensity fluctuations were measured for three independent samples and each measurement was repeated 20–30 times. Autocorrelation functions were fitted using a two-component model and diffusion times were calculated.

Cell culture

Cell lines were purchased from ATCC or other recognized cell depositories (Institute of Pathology, University Hospital of Basel, Switzerland and RIKEN Cell Bank, Ibaraki, Japan) who perform authentication and quality-control tests on all distribution lots of cell lines (Witzigmann *et al.*, 2016b). In addition, we performed authentication tests for all cell lines based on morphology check by microscope. All human cell lines were cultured at 37°C under 5% CO₂ and saturated humidity in Dulbecco's modified Eagle's culture medium high glucose (DMEM, Sigma-Aldrich) supplemented with 10% fetal calf serum (Amimed), penicillin (100 units/mL, Sigma-Aldrich), and streptomycin (100 µg/mL, Sigma-Aldrich). Stable Ntcp expressing liver derived cell lines, that is HepG2 *SLC10A1* and HuH7 *SLC10A1*, were created by lentiviral transduction as published previously (Ni *et al.*, 2014). For uptake experiments, different cell lines were seeded at a density of 2.5×10^4 cells/cm² and allowed to adhere for 24 h. For confocal laser scanning microscopy experiments, cells were grown on poly-D-lysine (Sigma-Aldrich) coated glass cover slips (#1.5, Menzel) or well plates (TPP).

Transfection of cell lines

For transient expression of the transporter, plasmids encoding for mNtcp (*Slc10a1*) or hNtcp (*SLC10A1*) were generated, amplifying the coding sequence from commercially obtained mRNA (Amsbio) by PCR. The following primers were used:

SLC10A1_for: 5'-ATGGAGGCCCAACGCGTCT-3',
SLC10A1_rev: 5'-CTAGGCTGTGCAAGGGGA-3';
Slc10a1_for: 5'-GTGTTCACTGGGTCGGAGGATG-3',

Slc10a1_rev1 5'-CAGGTCCAGAGCAAATACTCATAGGAG-3'.

Subsequently the amplicons were ligated into pEF6-V5/HIS (Invitrogen), followed by sequence verification (Microsynth). The resulting plasmids *Slc10a1*-pEF6 and *SLC10A1*-pEF6 and Lipofectamine 3000 (Sigma-Aldrich) were used for transfection of human cell lines. A standard transfection protocol was developed as follows: Plasmid DNA and P3000 reagent were diluted in Opti-MEM (Sigma-Aldrich) and rapidly mixed with Lipofectamine 3000 diluted Opti-MEM using a DNA-to-Lipofectamine 3000 w/v ratio of 3. After 5 min incubation, the transfection mix was added to adhered cells at a plasmid DNA concentration of 1 µg/mL. Control cells were either transfected with empty pEF6 vector or treated with Opti-MEM alone.

Assessment of cytocompatibility of nanoparticles

To assess the cytocompatibility of nanoparticles modified with different Myrcludex B derived peptides a MTT cell viability assay was performed. Wild type HeLa cells, liver-derived wild type HepG2 cells and HepG2 *SLC10A1* were seeded and cultured as described above. Nanoparticles were added to cells at final concentrations of 0.25 mM – 8 mM. After 24 h, MTT reagent (Sigma-Aldrich) was added to cells for 4 h. Formazan dye crystals were solubilized for 2 h using a mixture containing 3% (v/v) sodium dodecyl sulfate (Sigma-Aldrich) and 40 mM hydrochloric acid in isopropanol (Sigma-Aldrich). Absorption of reduced MTT and background signals was measured using a Spectramax M2 microplate reader at 570 nm and 670 nm, respectively. Control cells treated with buffer were used to calculate relative cell viability.

Uptake of nanoparticles in vitro

To assess the uptake rate and intracellular localization of nanoparticles, cell lines were incubated with different concentrations of nanoparticles at 37°C or 4°C. Nanoparticles were loaded with 5 (6)-carboxyfluorescein (payload) and/or incorporated Dil in their phospholipid-membrane. Myrcludex B derived peptides were fluorescently labeled if necessary as indicated above. At the indicated time points, confocal laser scanning microscopy or flow cytometry were used for qualitative and quantitative analysis, respectively.

Competitive inhibition experiments in vitro

NTCP-specific uptake of nanoparticles was investigated by pre-incubation with 400 nM free Myrcludex B fluorescently labeled with Atto-565 or Atto-488 as indicated.

Binding mechanism studies in vitro

The hepatic cell dependent binding mechanism of nanoparticles was investigated by pre-incubation with 300 µg/mL heparin sulfate.

Uptake mechanism studies on NTCP mediated internalization in vitro

The uptake mechanism of nanoparticles into HepG2 *SLC10A1* cells was investigated using different pharmacological pathway inhibitors as described previously (Lunov et al., 2011). Cells were pre-incubated using 100 µg/mL colchicine (micropinocytosis inhibitor), 10 µg/mL chlorpromazine (inhibitor of clathrin-mediated endocytosis), or 25 µg/mL nystatine (inhibitor of caveolin-mediated endocytosis) for 30 min before addition of nanoparticles.

Confocal laser scanning microscopy

At indicated time points, cell nuclei were counterstained for 5 min using 1.0 µg/mL Hoechst 33342 (Sigma-Aldrich), washed with PBS and embedded using ProLong Gold antifading reagent (Invitrogen Life Technologies). For live cell imaging, cell nuclei were counterstained with Hoechst 33342, and if indicated cell membranes were stained with Cell Mask Deep Red Plasma Membrane Stain (1.0 µg/mL, Thermo Fisher Scientific) and NTCP was stained using fluorescently labeled Myrcludex B. Confocal laser scanning microscopy analysis was performed using an Olympus FV-1000 inverted microscope (Olympus Ltd.), equipped with a 60 × PlanApo N oil-immersion objective (numerical aperture 1.40).

Flow cytometry analysis

To quantify the uptake rate of nanoparticles into non-hepatic and hepatic cell lines with different NTCP expression levels, flow cytometry analysis was performed. Cells were detached using 0.25% trypsin/EDTA (Sigma-Aldrich), washed twice with PBS and re-suspended in PBS containing 1% fetal calf serum, 0.05% NaN₃, and 2.5 mM EDTA. At least 10,000 cells per setting were analyzed using a FACS Canto II flow cytometer (Becton Dickinson). Doublets were excluded and Dil or CF signals were measured. Relative mean fluorescence intensities (MFI) of Dil or CF signals normalized to untreated cells were calculated using Flow Jo VX software (TreeStar).

High-content screening

To quantify the transfection of HepG2 cells deficient or expressing NTCP using DNA loaded nanoparticles, high-content screening was performed as described previously (Lin et al., 2013). Cells were seeded in 96-well cell culture dishes, were allowed to adhere for 24 h, and treated with lipid nanoparticles at a DNA concentration of 1.5 µg/mL. To assess the transfection efficacy using high-content screening, cells were fixed with 3% paraformaldehyde 24 h post treatment and cell nuclei were counterstained with Hoechst 33342. Plates were scanned and analyzed using a Cellomics Array-Scan VTI (Thermo Scientific).

Zebrafish embryo culture

Zebrafish embryos (*Danio rerio*) are a well-established vertebrate screening model for engineered nanomaterials (Campbell et al., 2018; Einfalt et al., 2018; Sieber et al., 2017). They were maintained in accordance with Swiss animal welfare regulations as described previously (Sieber et al., 2017). In brief, eggs from wild type ABC/TU and transgenic kdrl:EGFPs843 adult zebrafish were maintained in media at 28°C. Formation of pigment cells was prevented by 1-phenyl 2-thiourea (PTU, Sigma-Aldrich).

Injection of nanoparticles into zebrafish embryos

To assess the systemic circulation of nanoparticles, samples were injected into transgenic kdrl:EGFPs843 zebrafish embryos (two dpf) as described previously (Sieber et al., 2017). In brief, calibrated volumes of 1 nL were injected into the duct of Cuvier of anesthetized and agarose-embedded zebrafish embryos using a micromanipulator (Wagner Instrumentenbau KG), a pneumatic Pico Pump PV830 (WPI), and a Leica S8APO microscope (Leica). The tail region of zebrafish embryos was imaged 1 h post injection (hpi) using an Olympus FV-1000 inverted confocal laser scanning microscope equipped with a 20 × UPlanSApo (numerical aperture 0.75) objective.

Targeting of xenotransplanted human cells in the zebrafish model

Human HEK293 cells deficient or overexpressing *SLC10A1* were detached from 6-well cell culture dishes using 1 mL pre-warmed DMEM, washed (5 min at 200 g) and resuspended in 10 µL DMEM. Human cells (3 nL) were injected into the duct of Cuvier of ABC/TU zebrafish embryos. As soon as transgenic human cells stopped circulating and remained in the caudal vasculature tail region (after approximately two hpi), nanoparticles (1 nL) were injected as described above. Brightfield and fluorescence images of the tail region were taken 1 hpi of nanoparticles.

Colocalization analysis. Binding of nanoparticles to HEK293 cells was analyzed using the JaCoP plug-in Fiji. Therefore, Pearson's Correlation Coefficient (PCC) was determined to assess the extent of colocalization (Bolte and Cordelières, 2006).

Radioactive labeling of nanoparticles with ¹¹¹In

Labeling of nanoparticles with ¹¹¹In was performed with modifications as described previously (van der Geest et al., 2015). Nanoparticles were prepared as described above in PBS at a total lipid concentration of 60 mM (including 3 mol% DSPE-DTPA). Size exclusion chromatography was used to exchange the buffer system to citrate buffered saline pH 5.4, fractions were pooled and finally concentrated using Amicon Ultra-4 centrifugal filter units (100 kDa size exclusion). Nanoparticles (30 µmol) were incubated with 40 µL of ¹¹¹InCl₃ (Mallinckrodt Pharmaceuticals) at 37°C for 45 min using a thermocycler. After incubation, ¹¹¹In labeled nanoparticles were purified using NAP-5

columns (GE Healthcare) by elution with sterile saline (B. Braun Medical Inc). Fractions of 250 μ L were collected and activity of each fraction was determined.

Planar imaging of mice in vivo

All mice experiments were carried out in accordance with German legislation on animal welfare. Female NMRI mice (6–8 weeks) were obtained from Janvier Laboratories. For planar imaging, mice were anesthetized with Isoflurane (Baxter) and ^{111}In labeled nanoparticles with a total activity of 8–10 MBq (corresponding to 100 μ L) were intravenously injected into the tail vein. Afterwards, the animals were placed in prone position (see **Figure 5—figure supplements 2A** and **3A**) on a planar gamma-imager (Biospace) equipped with a high energy collimator as described previously (**Müller et al., 2013**; **Wischnjow et al., 2016**). Images were recorded at the indicated time points with 10 min acquisition time.

Planar imaging of harvested organs from mice and rats ex vivo

For planar imaging of organs, animals were anesthetized with Isoflurane (Baxter) and ^{111}In labeled nanoparticles were intravenously injected into the tail vein. Animals were sacrificed 15 min or 1 h post injection, organs were harvested and placed on a planar gamma-imager (Biospace) equipped with a high energy collimator. Images were recorded at the indicated time points with 10 min acquisition time.

Quantitative organ biodistribution of nanoparticles in mice ex vivo

For biodistribution studies, ^{111}In labeled nanoparticles with a total activity of 1–2 MBq (corresponding to 100 μ L) were intravenously injected into the tail vein of wild type mice. Animals were sacrificed ($n = 3$ per nanoparticle administration) 1 h post injection, organs were harvested and the radioactivity in each organ was measured with a Berthold LB 951G gamma counter. Each organ-associated activity was related to the injected dose. The percentage of injected dose (%ID) per organ was calculated using standard values for organ weights (**Mühlfeld et al., 2003**).

Fluorescence imaging of nanoparticles in tissue cryo-sections

Nanoparticles incorporating 1 mol% Dil were intravenously injected into the tail vein of wildtype mice. Animals were sacrificed 1 h post injection and organs were snap-frozen in liquid nitrogen. Cryo-sections of 16 μ m were mounted on Superfrost Plus Ultra microscope slides (Thermo Fisher Scientific) and counterstained with Hoechst 33342 (2 μ g/mL). Slides were embedded in Prolong Gold Antifade Mountant (Thermo Fisher Scientific), sealed with nail polisher and analyzed using an Olympus FV-1000 inverted confocal laser scanning microscope equipped with a 40x UPlanFL N oil-immersion objective (numerical aperture 1.30).

Immunohistochemistry of targeting ligand in tissue sections

After intravenous tail vein injection of nanoparticles, the mice were euthanized, organs were harvested, rinsed with PBS and immediately placed in a 4% formaldehyde solution in PBS. After fixation for 24 h, organs were dehydrated and embedded in paraffin. Sections of 5 μ m thicknesses were cut using a microtome MICROM HM 355, placed onto a microscope slide and dried at 37°C. After dewaxing and rehydration, epitope retrieval was performed. The primary antibody against Myr-preS2-31 (MA18/7, kind gift from Wolfram Gerlich) was added overnight at 4°C, before incubation with the secondary antibody. Finally, slides were counterstained with hemalum (Merck KGaA) for 10 min, blued with tap water and mounted using Aquatex (Merck Millipore).

Immunofluorescence imaging of liver cryo-sections

Animals were sacrificed 3 h post injection of nanoparticles and liver cryo-sections (16 μ m) were prepared as described above. Slides were stained using primary antibodies against Myr-preS2-31 (MA18/7, 1:100 dilution) and *Slc10a1* (provided by Prof. Bruno Stieger, University Zürich, 1:100 dilution). Finally, cell nuclei were counterstained with Hoechst 33342 (2 μ g/mL) and analyzed by confocal microscopy as described above.

Statistical analysis

Statistical analysis for all experiments was performed by one-way analysis of variance (ANOVA) followed by Bonferroni post-hoc test using OriginPro 9.1 software (OriginLab Corporation). Differences between groups were considered to be statistically significant at the indicated p-values.

Acknowledgements

We thank M Affolter, HG Belting and N Schellinx for providing zebrafish eggs, K Leotta for support with mice experiments, S Meßnard for sectioning of paraffin-embedded tissue, P Scheffele and L Burklé for support with cryo-sectioning, and H Heerklotz and D Eckhardt for DSC and PPC measurements.

doi: 10.1002/smll.201904716.

Highlights: Prolonged blood circulation half-life time is a prerequisite for successful nano-particle-based therapies. The most common approach to extend blood circulation lifetime is the decoration of nanoparticles with polyethylene glycol (PEG). However, immune reactions to PEG may significantly reduce treatment efficiency, especially in the case of repeated administration. In this study, we describe the synthesis and use of a possible alternative to PEG: bisalkyl polysarcosine (BA-pSar). We show that BA-pSar can be synthesized with defined chain lengths and low polydispersity. BA-pSar was successfully incorporated into liposomal formulations and enhanced circulation behavior while reducing macrophage recognition in a similar manner to PEG, as determined in the zebrafish embryo animal model. Moreover, BA-pSar can be end group modified to reduce complement activation and thereby reduces immune reactions compared to PEG.

Poly(Sarcosine) Surface Modification Imparts Stealth-Like Properties to Liposomes

Circulation lifetime is a crucial parameter for a successful therapy with nanoparticles. Reduction and alteration of opsonization profiles by surface modification of nanoparticles is the main strategy to achieve this objective. In clinical settings, PEGylation is the most relevant strategy to enhance blood circulation, yet it has drawbacks, including hypersensitivity reactions in some patients treated with PEGylated nanoparticles, which fuel the search for alternative strategies. In this work, lipopolysarcosine derivatives (BA-pSar, bisalkyl polysarcosine) with precise chain lengths and low polydispersity indices are synthesized, characterized, and incorporated into the bilayer of preformed liposomes via a post insertion technique. Successful incorporation of BA-pSar can be realized in a clinically relevant liposomal formulation. Furthermore, BA-pSar provides excellent surface charge shielding potential for charged liposomes and renders their surface neutral. Pharmacokinetic investigations in a zebrafish model show enhanced circulation properties and reduction in macrophage recognition, matching the behavior of PEGylated liposomes. Moreover, complement activation, which is a key factor in hypersensitivity reactions caused by PEGylated liposomes, can be reduced by modifying the surface of liposomes with an acetylated BA-pSar derivative. Hence, this study presents an alternative surface modification strategy with similar benefits as the established PEGylation of nanoparticles, but with the potential of reducing its drawbacks.

Thereby, one of the main goals of liposomes is to protect the entrapped drug while also reducing its off-site toxicity, as shown for multiple formulations.^[5–8] To this end, increasing on-target tissue concentration is a key aspect which can be achieved both by nontargeted and targeted liposomes.^[9–12] In this regard, a crucial point is the prolongation of systemic circulation lifetime. It is well-known that upon injection the majority of conventional (plain) liposomes are cleared rapidly from the blood stream by cells of the mononuclear phagocyte system.^[13–15] To enhance circulation times, a variety of approaches to modify the surface of liposomes emerged,^[16–18] yet ultimately polyethylene glycol (PEG) established itself as gold standard in the early 1990s aiming at decreasing opsonization.^[19–21] PEGylation not only reduces but also alternates the recognition of nanoparticles by complement factors and opsonins, resulting in a decreased nanoparticle recognition and clearance by macrophages.^[22,23] Manipulating opsonization, including the reduction of complement activation thus is

one of the main goals in preventing rapid clearance.

Today, surface modifications of liposomes are mostly realized with amphiphilic lipid-polymer conjugates like 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(polyethylene glycol)-2000] (DSPE-mPEG2k).^[24,25] Despite the benefits and being considered mostly nonimmunogenic, phospholipid-PEG conjugates have also demonstrated some drawbacks over the

1. Introduction

Nanomedicines have been investigated and used intensely over the past decades for several biomedical applications.^[1] With numerous products already approved and a variety of preparations in clinical trials, liposomes are the most advanced and successful nanomedicine in clinic.^[2–4]

last decade. Anti-PEG antibodies are a major concern regarding the clearance of intravenously administered liposomes modified with PEG,^[26,27] frequently culminating in the rapid clearance of injected liposomes.^[28,29] The occurrence of pre-existing anti-PEG antibodies even in healthy individuals has increased in everyday life due to exposure to PEG-containing products.^[30] Besides this so-called accelerated blood clearance phenomenon, it transpired that both, the anchoring phospholipid and PEG itself are likely to cause specific and nonspecific^[31] immune reactions. Such reactions are often caused by complement activation^[32,33] and can lead to hypersensitivity reactions (HSRs) possibly triggering anaphylaxis.^[34]

The negative charge at the phosphate group of DSPE-PEG derivatives is predominantly linked to this complement induction.^[35,36]

Conclusively, the development of alternative surface modifications offers an interesting possibility to circumvent the above-mentioned limitations of PEG derivatives.^[37–39] For this purpose, a multitude of hydrophilic materials has been proposed.^[40–45]

In this work, we report the synthesis of the lipid-like amphiphile bisalkyl polysarcosine (BA-pSar) and its successful incorporation into the lipid bilayer of preformed liposomes. It was demonstrated earlier that pSar has properties similar to PEG, comprising high water-solubility, flexibility, and low immunogenicity *in vitro*,^[46,47] making it a promising candidate for surface modification of liposomes.^[48] The aim of this study was to demonstrate that surface modification using pSar-lipopolymers is a valuable strategy to increase circulation half-life of liposomes while also ensuring good biocompatibility (i.e., low complement activation). After synthesis, physicochemical properties of pSar-modified liposomes were compared with PEGylated and nonsurface-modified liposomes regarding their size, polydispersity, and zeta potential. To evaluate the extend of BA-pSar inserted into the bilayer, we determined the incorporation efficiency via high performance liquid chromatography (HPLC) with increasing amounts of BA-pSar added to preformed liposomes using the post-insertion method.

In order to study the pharmacokinetics of liposomes with different surface modifications, we selected the zebrafish model as a validated *in vivo* tool to assess circulation properties and macrophage clearance.^[49]

Addressing the occurrence of HSR, we also investigated the complement activation potential of liposomes modified with BA-pSar and an optimized acetylated derivative of pSar (pSar₁₀₂Ac) with net-neutral charge.

2. Results and Discussion

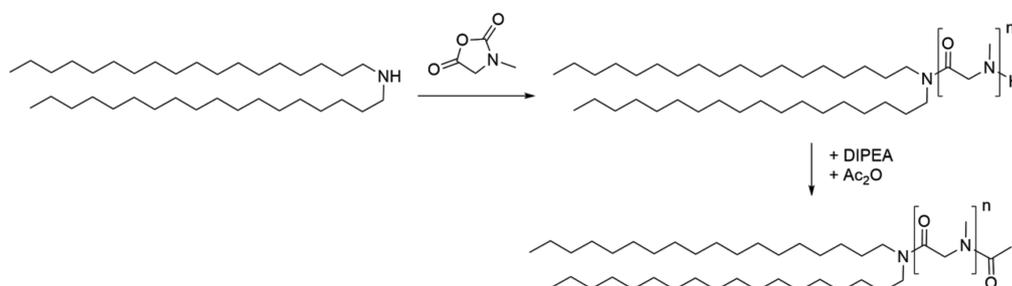

2.1. Synthesis of Bisalkylated Lipopolysarcosine

One part of the present work was the synthesis of a bisalkylated polysarcosine. The synthesis (Scheme 1) was adapted and modified from the literature.^[45] The sarcosine-*N*-carboxyanhydride was synthesized and purified before the polymerization was started by the addition of the bisalkylamine. In contrast to monoalkylated pSar lipopolymers, solvent condition had to be adjusted due to the hydrophobicity of the initiator. Thus, polymerizations were performed in benzonitrile. After completion of the reaction, which was assured by Fourier-transform infrared spectroscopy, the polymer was precipitated in cold diethylether and purified via dialysis (Figure 1).

¹H NMR experiments demonstrate that the deviation between obtained and calculated degrees of polymerization is below 10% (Table 1 and Figure 1A). In line with MALDI-TOF MS (matrix-assisted laser desorption/ionization-time of flight mass spectrometry) ¹H DOSY (diffusion-ordered spectroscopy) NMR shows the presence of only one diffusing species confirming the absence of free initiator and water-initiated polymer (Figure 1B). The discrepancy between the molecular weights determined by HFIP-GPC (hexafluoro-2-isopropanol-gel permeation chromatography) and NMR can be explained with the uncommonly high values of polymethylmethacrylate (PMMA) in HFIP.^[46]

The reported method is a simple way to vary lipopolymer architectures in a one-step polymerization. Moreover, polysarcosine bears the potential for further end group modification, due to the terminal amine end group (Scheme 1). To maintain the nonionic nature of the polymer, pSar end groups were acetylated with acetic anhydride in a post-polymerization manner without any influence on the molecular weight distribution or chemical integrity of the polymer (Figure 2A,B). In addition, MALDI-ToF analysis of BA-pSar₁₀₂ was performed and is displayed in Figure 2C. Despite severe mass discrimination, the spectrum reveals the full incorporation of the bisalkyl amine initiator (dioctadecylamine) without any detectable side products, i.e., initiation by traces of water or other impurities. Enlargement of the most intense peaks (Figure 2D) shows degrees of polymerization of $X_n = 19,20$ and sub-populations due to sodium and potassium ionization.

The second part of this work was focused on the incorporation of synthesized pSar derivatives into the lipid bilayer of

Scheme 1. Synthesis of BA-pSar₁₀₂ based on nucleophilic ring opening polymerization of sarcosine NCA and formation of BA-pSar₁₀₂Ac via end group modification (acetylation).

liposomes and the comparison with DSPE-mPEG2k. Therefore, BA-pSar₁₀₂, BA-pSar₁₀₂Ac, and DSPE-mPEG2k were used to modify the surface of preformed 1,2-distearoyl-*sn*-glycero-3-phosphocholine (DSPC)/cholesterol (Chol) liposomes. The lipid ratios were chosen to be similar to the formulation of an approved PEGylated liposome formulation, namely, Doxil. Doxil is composed of hydrogenated soya phosphatidylcholine, Chol, and DSPE-mPEG2k at a molar ratio of 57:38:5.^[50]

2.2. Characterization of Liposomes

The hydrodynamic diameter and polydispersity index (PDI) of different liposome formulations were determined before and after purification of liposomes from noninserted lipopolymer conjugates using dynamic light scattering (DLS). Zeta potential was measured after purification. Results for size and PDI before and after post-insertion of lipopolymers followed by purification are displayed in **Table 2**. Within the estimated errors, results obtained for size and PDI were comparable for all preparations and did not change over the process of post-insertion. Size was approximately 120 nm and PDI was ≤ 0.1 , indicating homogenous size distributions for all formulations.

Figure 3 shows Cryo-TEM (cryogenic transmission electron microscopy) images displaying the morphology of representative liposomes which were selected for further in vitro and zebrafish experiments. Unmodified as well as surface-modified formulations show a narrow size distribution. Neither PEGylation nor modification with BA-pSar₁₀₂ induced significant changes in liposomal morphology or size distribution. Cryo-TEM

images are in good agreement with size values obtained by DLS measurements.

2.3. Zeta Potential of Liposomes

To assess the surface charge shielding potential of the different surface modifications, an additional set of liposomal formulations was prepared containing the cationic lipid 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP, 10 mol%) (**Figure 4A**). Measurements of liposomes without DOTAP (**Figure 4B**) revealed only slight differences in zeta potential due to the neutral character of the formulation. Addition of DOTAP allowed to compare the influence on surface charge shielding of different formulations using zeta potential measurements. Notably, size characteristics for all preparations were comparable (Supporting Information, **Figure S1**). Unmodified liposomes showed a relatively high zeta potential of about +46 mV. In contrast, the zeta potential for liposomes modified with DSPE-mPEG2k and BA-pSar₁₀₂ was reduced drastically, as already reported previously.^[51] PEGylation resulted in a zeta potential of about -6 mV, whereas liposomes modified with pSar had a zeta potential around +9 mV, suggesting an effective shielding of charge. The slightly negative zeta potential for PEGylated liposomes on the one hand is probably due to the negative charge at the phosphate moiety of DSPE-mPEG2k. The slightly positive charge of BA-pSar₁₀₂-modified liposomes on the other hand can be attributed to the terminal secondary amine of pSar, which is protonated at physiological pH. Measurements of liposomes modified with end-capped pSar (BA-pSar₁₀₂Ac) displayed a zeta potential of around +2 mV. Since BA-pSar₁₀₂Ac bears no charge, this suggests that an effective shielding of the positive charge introduced by DOTAP was achieved with this formulation.

Table 1. Synthesized sarcosine-based lipopolymers with an initial monomer to initiator ratio of $M/I = 90$, molecular weights and dispersity indices.

Polymer	Initiator/end-group	M_n (Calc) ^{a)} [kg mol ⁻¹]	M_n (GPC) ^{b)} [kg mol ⁻¹]	M_n (NMR) ^{c)} [kg mol ⁻¹]	PDI
BA-pSar ₁₀₂	DODA/H	6.9	38.5	7.8	1.2
BA-pSar ₁₀₂ Ac	DODA/Ac	7.0	38.7	7.8	1.2

^{a)} Calculated molecular weight (based on M/I ratio); ^{b)} Determined by HFIP-GPC using PMMA-standards;

^{c)} Determined by ^1H NMR via end-group analysis.

2.4. Incorporation Efficiency

For all surface-modified liposomes, DSPE-mPEG2k, BA-pSar₁₀₂, and BA-pSar₁₀₂Ac incorporation efficiency into the liposomal bilayer was monitored via HPLC.

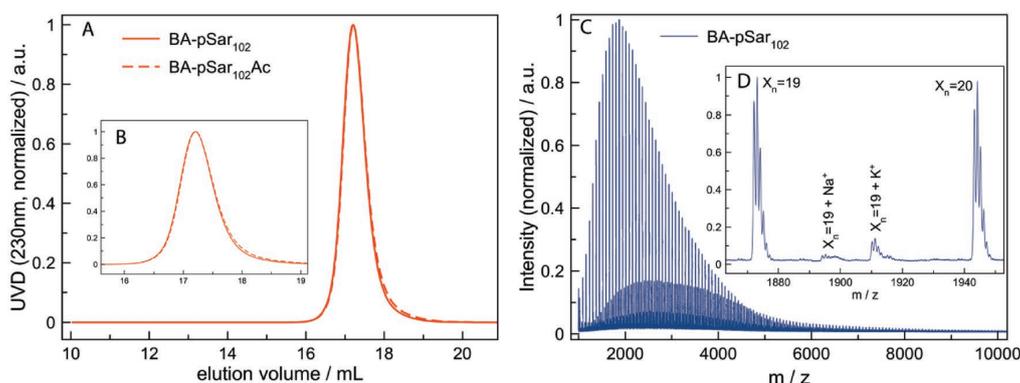

Figure 2. A) Normalized HFIP-GPC traces of BA-pSar₁₀₂ and BA-pSar₁₀₂Ac. B) Enlarged HFIP-GPC traces of BA-pSar₁₀₂ and BA-pSar₁₀₂Ac for a better comparison. C) Normalized MALDI-ToF spectrum of BA-pSar₁₀₂. D) Enlargement of the most intensive peaks of MALDI-ToF spectrum of BA-pSar₁₀₂.

In preliminary tests, different amounts of BA-pSar₁₀₂ (1–15 mol%) were dried from stock solutions, hydrated with preformed liposomes, and post-insertion into the liposomal bilayer was analyzed. Thereby, incorporation of at least 4.5 mol% was achieved by hydrating 7.5 mol% dried BA-pSar₁₀₂ or BA-pSar₁₀₂Ac with preformed liposomes. Excess conjugate was removed by ultrafiltration. These results correspond to an incorporation efficiency of approximately 60% of added conjugate. All further experiments therefore were conducted using the same setup, adding preformed liposomes to 7.5 mol% of dried BA-pSar₁₀₂ or BA-pSar₁₀₂Ac, respectively. When hydrating 5 mol% of dried DSPE-mPEG2k in an analogous manner, complete incorporation was observed. Incorporation efficiency results obtained after purification are shown in Table 3.

In summary, BA-pSar₁₀₂ and BA-pSar₁₀₂Ac were successfully incorporated into the lipid bilayer, resulting in liposomes with a narrow size distribution. Liposomes modified with lipopolysarcosines also showed effective surface charge shielding, comparable with findings for PEGylated liposomes. To further evaluate the potential use of BA-pSar₁₀₂-modified liposomes, clearance by macrophages and circulation properties were investigated *in vivo* in the zebrafish model.

2.5. Assessment of Liposome Pharmacokinetics In Vivo

Fluorescently labeled liposomes with different surface modifications (i.e., DSPE-mPEG2k as positive control for stealth properties or BA-pSar₁₀₂) and unmodified (conventional) liposomes (negative control) were injected into the blood circulation of zebrafish larvae. No acute signs of toxicity (i.e., denaturation of tissue fluids or yolk, heart failure) nor long-term effects

Table 2. Physicochemical characterization of liposomal formulations after purification. Values are means \pm SD, $n = 3$.

Formulation	Hydrodynamic diameter [nm]	PDI
DSPC/Chol/Dil	107 \pm 10	0.05 \pm 0.02
DSPC/Chol/Dil/DSPE-mPEG2k	113 \pm 9	0.06 \pm 0.02
DSPC/Chol/Dil/BA-pSar ₁₀₂	123 \pm 10	0.09 \pm 0.02
DSPC/Chol/Dil/BA-pSar ₁₀₂ Ac	130 \pm 2	0.05 \pm 0.02

including malformations or increased mortality were observed (data not shown), indicating the biocompatibility of all liposome formulations including both surface modifications.

At 3 h post injection (hpi), all liposome formulations demonstrated a diffusive fluorescence staining without accumulations in the posterior caudal vein (PCV) region (Figure 5). Recently, it has been shown that endothelial cells in the PCV express stabilin receptors which can scavenge liposomes and thereby prevent blood circulation.^[52] However, an increased colocalization (yellow) of conventional liposomes (red) and macrophages (green) was already detected at this time point indicating macrophage clearance (white arrows, Figure 5).

A clear difference in circulation characteristics of different liposome formulations was observed 24 hpi (Figure 5). Unmodified DSPC/Chol liposomes demonstrated decreased circulation properties indicated by a dotted staining pattern (i.e., clearance by stabilin scavenger receptors). In contrast, both surface-modified liposomes (i.e., DSPE-mPEG2k and BA-pSar₁₀₂) still demonstrated a prolonged circulation lifetime.^[53] Strikingly, macrophage clearance of unmodified liposomes increased significantly as compared to surface-modified liposomes (indicated by yellow color of colocalization).^[54] Both PEG and pSar prevented macrophage clearance signifying their ability to confer a stealth effect to the liposomes (Figure 5). This can be explained by the advantageous properties of lipopolymer surface modification including decreased opsonization and steric stabilization. In addition, this prevents time-dependent formation of aggregates via steric stabilization preferentially sequestered by macrophages. Conclusively, BA-pSar₁₀₂-modified liposomes outperformed unmodified control liposomes (i.e., DSPC/Chol) with favorable pharmacokinetic characteristics—an improved blood circulation lifetime and a decreased macrophage clearance. Moreover, BA-pSar₁₀₂-modification of liposomes resulted in similar *in vivo* properties as DSPE-mPEG2k liposomes, which are considered as the gold standard for long circulating, stealth liposomes.

2.6. In Vitro Complement Activation

Figure 6 shows the elevated sC5b-9 levels after incubation of liposomes and controls with three individual serum samples.

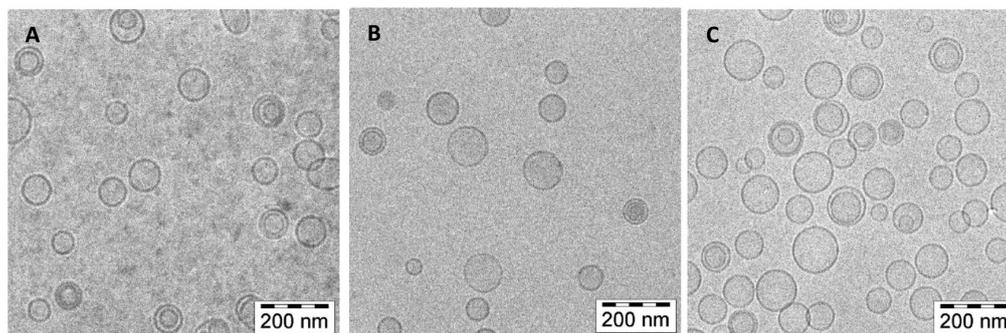

Figure 3. Cryo-TEM images showing the morphology of different liposomal formulations. A) DSPC/Chol/Dil, B) DSPC/Chol/Dil/DSPE-mPEG2k, and C) DSPC/Chol/Dil/BA-pSar₁₀₂.

As expected there are variations in sC5b-9 levels in the sera of different donors, as can be seen for the negative control (HBS, HEPES buffered saline). Compared to HBS, PEGylated liposomes induced a 1.5- to 2.5-fold increase in complement activation (C activation) in all tested sera, which is in good accordance with values obtained from literature.^[36] For BA-pSar₁₀₂-modified liposomes, an increase in C activation was observed, resulting in 2.5- to 5-fold higher sC5b-9 levels as compared to HBS. Charged liposomes are known to elicit the complement system and cationic liposomes are known

to do so via the alternative pathway.^[55] Thus, C activation enhancement by BA-pSar₁₀₂ compared to DSPE-mPEG2k comes as no surprise as the N-terminus of the polymeric chain bears a secondary amine, which is present in its ammonium salt form under physiological conditions. In a similar manner, the negative charge at the phosphate moiety of DSPE-PEG is well known to stimulate C activation.^[35] In order to exploit the advantageous synthetic features of lipopolysarcosine, the optimized end-capped BA-pSar₁₀₂Ac derivative was incorporated into liposomes. Interestingly, BA-pSar₁₀₂Ac-modified liposomes demonstrated improved properties with decreased complement activation. Compared to HBS only a 2.5-fold increase in sC5b-9 levels in serum C, and only 1.5-fold increase in serum A and strikingly no increase in serum B was observed.

Our findings show that replacing the anchoring DSPE with dioctadecylamine and subsequent end-capping of pSar with a neutral acetyl moiety results in a significantly decreased C activation in two of the three tested sera when comparing DSPE-mPEG2k with BA-pSar₁₀₂Ac. This most likely is a result of omitting the charges both at the anchor (hydrophilic-hydrophobic interface) and the polymeric chain, as it was previously demonstrated for free (nonliposomal incorporated) polymers.^[47]

3. Conclusion

In this study, we present the one step synthesis of a lipopolysarcosine derivative enabling controlled modification of liposomes to enhance systemic circulation. The controlled polymerization conditions allow for an accurate degree of polymerization resulting in the precise tailoring of pSar chain length while keeping polydispersity low. Due to the reactive

Quantitative analysis of macrophage clearance was performed using PCC. Values are means \pm SD, $n = 6$. * $p < 0.05$ or ** $p < 0.01$ (one-way analysis of variance (ANOVA) followed by Bonferroni post hoc test) as compared to conventional liposomes composed of DSPC/Chol/Dil.

amino group, further diversification can be achieved in a simple post-polymerization modification step without altering the polydispersity of the precursor polymer. Using this approach, the positive net charge of BA-pSar₁₀₂ was omitted by acetylation of the terminal amine. Subsequently, we were able to successfully incorporate BA-pSar₁₀₂ and BA-pSar₁₀₂Ac into the lipid bilayer of preformed liposomes using post-insertion technique.

Liposome characterization including the determination of size and morphology revealed a monodisperse size distribution with mostly unilamellar vesicles. Zeta potential measurements of surface-modified liposomes demonstrated an effective shielding of surface charge. In contrary to modification with DSPE-mPEG2k and BA-pSar₁₀₂, which still resulted in a slightly negative or positive zeta potential, BA-pSar₁₀₂Ac-modified

liposomes unveiled an almost net-neutral surface charge. Furthermore, the alternative hydrophobic anchor not only circumvents the negative charge that comes with the widely used DSPE-PEG derivatives but also provides sufficiently firm binding for the relatively large pSar chain into the bilayer. Moreover, BA-pSar-modified liposomes also featured prolonged circulation properties and decreased recognition by macrophages in the zebrafish model similar to PEGylated liposomes. Finally, liposome-mediated C activation could be reduced by modification of liposomes with an end-capped pSar derivative. All these results confirm that surface modification of liposomes with pSar or its derivatives is a promising alternative to well-established PEGylation strategies, especially in regard of reducing potential HSR. Equipped with an easily modifiable

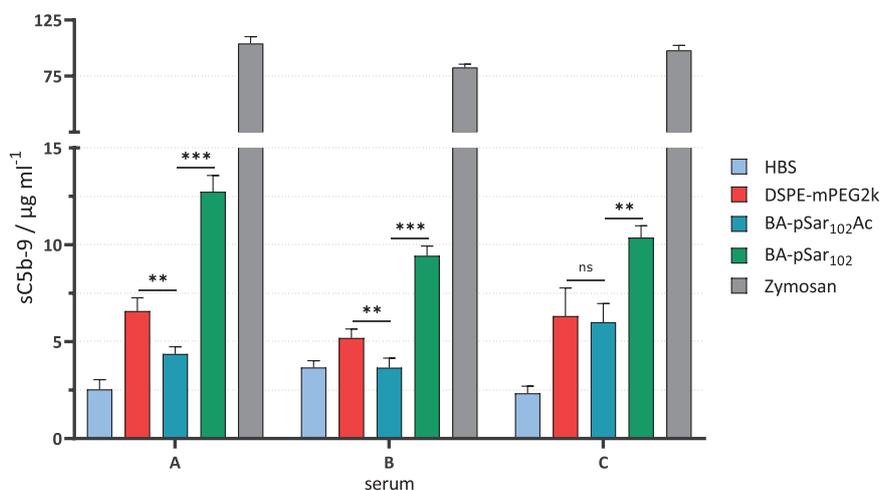

Figure 6. Complement activation of different liposomal formulations and controls. A–C) Samples were incubated for 1 h with human serum of three individuals. end-group, incorporation of lipopolysarcosine and further functionalization is also a promising option for the exploitation of active drug targeting or combination therapies.

4. Experimental Section

Materials: *n*-Hexane (Fischer Scientific, Waltham, USA) was distilled from Na/K. Benzonitrile was purchased from Sigma Aldrich (Steinheim, Germany), dried over CaH₂, and freshly distilled prior to use. Tetrahydrofuran (THF) and toluene were purchased from Fischer Scientific (Waltham, USA), dried over Na, and freshly distilled prior to use. HFIP was purchased from Fluorochem (Hadfield Derbyshire, UK). Dioctadecylamine was purchased from Fluka (St. Gallen, Switzerland) and dried at 40 °C under vacuum (1×10^{-3} mbar) for 24 h. Diphsogene was purchased from Alfa Aesar (Ward Hill, MA, USA) and deuterated solvents from Deutero GmbH (Kastellaun, Germany).

DSPC and DSPE-mPEG2k were generously donated by Lipoid GmbH (Ludwigshafen, Germany). DOTAP was obtained from Merck (Darmstadt, Germany). 1,1'-dioctadecyl-3,3',3'-tetramethylindocarbocyanine perchlorate (DiI) was purchased from Invitrogen (Thermo Fisher Scientific, Waltham, USA). Chol was purchased from Sigma Aldrich (Steinheim, Germany). Other chemicals were purchased from Sigma-Aldrich (Steinheim, Germany) and used as received unless stated otherwise. Human serum samples of ten healthy donors were obtained from the University Medical Center Freiburg. Sera were stored at a temperature of -80 °C until used.

Synthesis of Sarcosine *N*-Carboxyanhydride: A total of 14.92 g (167.4 mmol) sarcosine, dried under vacuum for 1 h, was weighed into a pre-dried, three-neck, round-bottom flask. A total of 300 mL of absolute THF was added under a steady flow of nitrogen, 16.2 mL (134 mmol) of diphsogene was added slowly via syringe, and the nitrogen stream was reduced. The colorless suspension was mildly refluxed for 3 h, yielding a clear solution. Afterward, a steady flow of dry nitrogen was led through the solution for another 3 h while the outlet was connected to two gas washing bottles filled with aqueous NaOH solution to neutralize phosgene. The solvent was evaporated under reduced pressure, yielding a brownish oil as a crude reaction product. The oil was dried under reduced pressure (1×10^{-3} mbar for 2 h) to obtain an amorphous solid, free of phosgene and HCl, confirmed by testing against a silver nitrate solution. The crude product was redissolved in 40 mL of THF

and precipitated with 300 mL of dry *n*-hexane. The solution was cooled to -18 °C and stored for 18 h to complete precipitation. The solid was filtered under dry nitrogen atmosphere and dried in a stream of dry nitrogen for 60–90 min and afterward under high vacuum for 2 h in the sublimation apparatus. The crude product was sublimated at 85 °C and 1×10^{-3} mbar. The product was collected from the sublimation apparatus in a glovebox on the same day. The purified product (110 mmol, 65% yield, colorless crystallites; melting point: 102–104 °C (lit: 102–105 °C)) was stored in a Schlenk tube at -80 °C.

¹H NMR (300 MHz, CDCl₃): δ /ppm = 4.22 (2H, s, $-\text{CH}_2-\text{CO}-$), 2.86 (3H, s, $-\text{CH}_3$).

Synthesis of Polysarcosine: Sarcosine NCA was transferred into a pre-dried Schlenk tube equipped with a stir bar under nitrogen counter flow and again flame-dried under high vacuum for 1 h. Subsequently, the NCA was dissolved in dry benzonitrile to yield a solution of 100 mg mL⁻¹ with respect to the NCA. 1/*n* equivalent of dioctadecylamine was dispersed in pre-dried toluene and added to the NCA solution. The solution was stirred at room temperature and kept at a constant pressure of 1.25 bar of dry nitrogen via a schlenk line to prevent impurities from entering the reaction vessel while allowing CO₂ to escape. Completion of the reaction was confirmed by Fourier transform infrared (FT-IR) spectroscopy (disappearance of the NCA related peaks (1853 and 1786 cm⁻¹)). After completion of the reaction, the polymer was precipitated in cold diethylether and centrifuged (4500 rcf at 4 °C for 15 min). After discarding the liquid fraction, new ether was added and the polymer was resuspended in a sonication bath. The suspension was centrifuged again and the procedure was repeated. The polymer was dissolved in water, dialyzed against MilliQ water and lyophilized, obtaining a colorless, stiff and porous solid. The yield after purification was 91% of the theoretically achievable mass of the polymer.

¹H NMR (400 MHz; CDCl₃): δ /ppm: 4.51–3.80 (204H; br; (2n)-CO-CH₂-NMe-); 3.12–2.62 (306H; br; (3n)-N-CH₃-); 1.83–1.00 (64H; br; $-(\text{CH}_2-(\text{CH}_2)_{16}-\text{CH}_3)_2$); 0.87 (6H; t; $-(\text{CH}_2-(\text{CH}_2)_{16}-\text{CH}_3)_2$).

Acetylation of Polysarcosine: 100 mg of polysarcosine (BA-pSar₁₀₂) was dissolved in 0.5 mL dimethylformamide (DMF), 10 equivalents (in respect to the calculated molecular mass of the polymer) of diisopropylamine were added and the solution was stirred for 30 min at room temperature. Afterward, 5 equivalents of acetic acid anhydride were added and the solution was stirred overnight at room temperature. The polymer was precipitated in cold ether and centrifuged (4500 rcf at 4 °C for 15 min). After discarding the liquid fraction, fresh ether was added, the polymer was resuspended in a sonication bath and

Table 4. Lipid compositions of prepared formulations.

Formulation	Initial molar ratio	Ratio after purification
DSPC/Chol/Dil	60:39:1	–
DSPC/Chol/Dil/DSPE-mPEG2k	55:39:1:5	55:39:1:4.8
DSPC/Chol/Dil/BA-pSar ₁₀₂	57:39:1:7.5	57:39:1:3.2
DSPC/Chol/Dil/BA-pSar ₁₀₂ Ac	57:39:1:7.5	57:39:1:3.4
DSPC/Chol/DOTAP	50:40:10	–
DSPC/Chol/DOTAP/ DSPE-mPEG2k	45:40:10:5	45:40:10:4.9
DSPC/Chol/DOTAP/BA-pSar ₁₀₂	47:40:10:7.5	47:40:10:3.1
DSPC/Chol/DOTAP/BA-pSar ₁₀₂ Ac	47:40:10:7.5	47:40:10:3.3

centrifuged afterward. This procedure was repeated. The polymer was dissolved in water, dialyzed against MilliQ water to remove excess of acetic acid and residual traces of DMF. After lyophilization, a colorless, stiff, and porous solid was obtained.

¹H NMR (400 MHz; CDCl₃): δ/ppm: 4.51–3.80 (204H; br; (2n)–CO–CH₂–NH–); 3.12–2.62 (306H; br; (3n)–N–CH₃–); 1.83–1.00 (64H; br; –CH₂–(CH₂)₁₆–CH₃); 0.87 (6H; t; –CH₂–CH₃).

¹H NMR spectra were recorded on a Bruker (Billerica, MA, USA) AC 400 at a frequency of 400 MHz, respectively. 2D NMR spectra as ¹H DOSY were recorded on a Bruker Avance III HD 400 at 400 MHz. All spectra were recorded at room temperature (25 °C) and calibrated using the solvent signals. Melting points were measured using a Mettler FP62 melting point apparatus at a heating rate of 2.5 °C min⁻¹. GPC was performed with HFIP containing 3 g L⁻¹ potassium trifluoroacetate as the eluent at 40 °C and a flow rate of 0.8 mL min⁻¹. The columns were packed with modified silica (PFG column particle size: 7 μm, porosity: 100 and 1000 Å). PMMA standards (Polymer Standards Services GmbH, Mainz, Germany) were used for calibration and toluene was used as the internal standard. A refractive index detector (G1362A RID) and an UV-vis detector (at 230 nm unless otherwise stated; Jasco, Gross-Umstadt, Germany, UV-2075 Plus) were used for polymer detection.

Preparation of Liposomes: Liposomes were prepared using the thin-film hydration method. For zebrafish experiments, 1 mol% Dil was added as a fluorescent label. Briefly, stock solutions of all components were prepared by dissolving dry powders in CHCl₃ and/or MeOH. Stock solutions were mixed in molar ratios according to Table 4. Organic stocks were removed using a rotary evaporator (Rotavapor R, Büchi, Essen, Germany) and lipid films were dried for at least 2 h to ensure complete removal of organic solvents. Lipid films were hydrated with HBS (140 mmol L⁻¹ NaCl, 10 mmol L⁻¹ Hepes (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), pH 7.4) resulting in a lipid concentration of 20 mmol L⁻¹. Dispersions were extruded 41 times through an 80 nm polycarbonate membrane. All steps were conducted at 65 °C. Phospholipid content was determined using Bartlett's Assay.^[56] For exact compositions of liposomes, see Table 4.

Post-Insertion of PEG- and pSar-Conjugates: DSPE-mPEG2k, BA-pSar₁₀₂, and BA-pSar₁₀₂Ac were inserted into preformed liposomes using the post-insertion technique.^[57,58] Briefly, organic stock solutions containing defined amounts of DSPE-mPEG2k, BA-pSar₁₀₂, and BA-pSar₁₀₂Ac were evaporated for several hours using an evaporation centrifuge (Concentrator 5301, Eppendorf, Hamburg, Germany). Dispersions of preformed liposomes then were added to the residue, vortex mixed, and incubated at 65 °C for 1 h under constant agitation (Thermomixer comfort, Eppendorf, Hamburg, Germany). To remove any noninserted conjugates, liposomes were washed three times with HBS using Vivaspin Turbo 4 ultrafiltration devices (100 kDa MWCO PES membranes, Sartorius, Göttingen, Germany) at 3000 rcf for 30 min. For molar ratios after purification see Table 4.

Particle Size and Zeta Potential Measurements: Mean hydrodynamic diameter, size distribution, and zeta potential were assessed using a Zetasizer Nano ZS (Malvern Instruments, Malvern, UK) and ZetaPals

Table 5. RP-8 column gradient. A: MeOH, B: NH₄OAc buffer pH 4.0, C: ACN. A methanol/water/acetonitrile (7:2:1) to methanol/acetonitrile (9:1) gradient was used to separate PEGylated samples on a C8 reversed phase column. Solvents contained 4 mmol L⁻¹ ammonium acetate.

Time	Flow [mL]	%A	%B	%C
0	0.75	70	20	10
5	0.75	70	20	10
15	0.75	90	0	10
25	0.75	90	0	10
30	0.75	70	20	10

instrument (Brookhaven Instruments Corp., Holtsville, USA). For size measurements, samples were diluted with HBS to 0.1 mmol L⁻¹ in disposable plastic cuvettes. Zeta potential was measured using a high concentration cell (Malvern Instruments, Malvern, UK) as described earlier.^[59] Liposomes were diluted to 1 mmol L⁻¹ with 10 mmol L⁻¹ HBS and measured immediately after dilution.

Cryo-TEM: Liposomes were diluted with HBS to achieve a final concentration of 5 to 10 mmol L⁻¹ lipid. About 3 μL were applied on a 400 × 100 mesh Quantifoil S 7/2 holey carbon film on a copper grid (Quantifoil Micro Tools GmbH, Jena, Germany). Excess liquid on the grid was removed with filter paper. The sample then was flash frozen by injection into liquid ethane. All sample preparation steps were conducted in a climate-controlled room using a CryoBox 340719 (Carl Zeiss, Oberkochen, Germany). Subsequent fixation of the grid on the sample rod (626-DH, Gatan, Warrendale, USA) and transfer of the rod into the TEM (Leo 912 Ω-mega, Carl Zeiss, Oberkochen, Germany) were conducted under nitrogen atmosphere at –183 °C. The instrument was operated at 120 kV and camera pictures (Proscan HSC 2, Oxford Instruments, Abingdon, USA) were taken with a 6300- to 12 500-fold magnification from different positions of the grid.^[60]

Quantification of Conjugate Incorporation: Using a Waters Alliance 2695 separation module (Waters, Milford, USA), mounted with RP-8 (Kinetex 5 μm C8 100 Å, 250 × 4.6 mm) and HILIC (hydrophilic interaction liquid chromatography, Luna 5 μm HILIC 200 Å, 250 × 4.6 mm; both Phenomenex, Torrance, USA) columns, an HPLC method was developed to separate polymer-conjugates from other lipid components. Standards were dissolved in MeOH, samples were diluted to approximately 0.5 mmol L⁻¹ with MeOH. DSPE-mPEG2k content was analyzed on an RP-8 column at 45 °C with the gradient shown in Table 5. BA-pSar₁₀₂ and BA-pSar₁₀₂Ac contents were analyzed on an HILIC column at 25 °C running the gradient as depicted in Table 6. The incorporation efficiency

Table 6. HILIC column gradient. A: MeOH, B: H₂O, C: NH₄OAc buffer (100 mmol L⁻¹ ammonium acetate buffer at pH 5.0), D: ACN. A complex gradient containing 5 mmol L⁻¹ ammonium acetate buffer was used to separate samples containing lipopolysarcosines.

of both polymer-conjugates was quantified with a Corona charged aerosol detector (Corona CAD ESA 542, Dionex, Sunnyvale, USA) after performing the post-insertion technique followed by a purification step. Data were analyzed with Empower 3.0 software (Waters, Milford, USA). Incorporation efficiency was calculated using the formula shown in Equation (1).

Equation (1). Incorporation efficiency of polymer-conjugates

$$IE = \frac{c_{cp} \times c_{lt}}{c_{ct} \times c_{lp}} \times 100\% \quad (1)$$

c_{cp} : polymer-conjugate concentration after purification

c_{ct} : theoretical polymer-conjugate concentration

c_{lp} : lipid concentration after purification

c_{lt} : theoretical lipid concentration

Zebrafish Experiments: Zebrafish larvae originating from adult Tg(mpeg1:Gal4;UAS:Kaede) were raised at 28 °C in zebrafish culture media.^[61] Pigment cell formation was prevented by the addition of 1-phenyl-2-thiourea to the zebrafish culture media at 24 h post fertilization. All zebrafish experiments were performed in accordance with Swiss animal welfare regulations. Calibrated volumes of 1 nL at 5 mmol L⁻¹ lipid concentration were injected directly into blood circulation via the duct of Cuvier. All injections were performed using a pneumatic PicoPump PV830 (WPI, Sarasota, Florida), and a Leica S8APO microscope (Leica, Wetzlar, Germany). Successfully injected zebrafish embryos (no yolk or heart injections) were kept at 28 °C and imaged 3 and 24 hpi using an Olympus FV-1000 inverted confocal laser scanning microscope (Olympus Ltd., Tokyo, Japan) equipped with a 20 × UPlanSApo (NA 0.75) objective. Macrophage clearance of liposomes was quantitatively assessed using colocalization analysis based on Pearson's correlation coefficient (PCC) using the JaCoP plugin from Fiji ImageJ.^[62,63]

Complement Activation: Activation of the complement cascade was analyzed by determining SC5b-9 (Protein S-bound terminal complement complex c5b-9) levels using an immunoassay kit (MicroVue SC5b-9 Plus EIA, Quidel, Santa Clara, USA).

In preliminary tests, liposome-mediated complement activation was investigated in freshly prepared human sera of 20 healthy donors. Sera of the three most sensitive individuals were chosen for further testing.

Applying the findings by Moghimi et al.^[64] where concentrations of 3–4 mg lipid mL⁻¹ serum were found to raise SC5b-9 levels the most, liposomes were diluted to 14.5 mmol L⁻¹ (approximately 14 mg mL⁻¹) with HBS. HBS was used as a negative control, Zymosan (0.5 mg mL⁻¹) served as positive control. All samples were incubated by mixing 1 part liposome dispersion with 4 parts human serum for 1 h at 37 °C under constant agitation. Following the incubation samples were diluted 100-fold (700-fold for Zymosan) with manufacturers dilution buffer and the assay was conducted as described in the manufacturers protocol.

Bacteria vs. antibiotics – Bridging infection modeling in *Danio rerio*

Jonas Buck, Patrick Hauswirth, Sandro Sieber, Beatrice Claudi, Dirk Bumann, Jörg Huwyler.

Manuscript ready for submission.

Highlights: Growing inefficiency of known antibiotic compounds towards pathogenic microorganism is a serious problem and the development of novel antibiotic compounds is very expensive. The zebrafish embryo animal model can serve as a tool to bridge the gap between *in vitro* and *in vivo* experiments in the development of nanomedicines. Here we describe the establishment of a zebrafish embryo *Salmonella* infection model for the screening of antibiotic compounds. Various model parameters (*i.e.*, the bacteria dose, the site of injection and temperature) were investigated. The optimized model was validated using two antibiotic compounds and could discriminate the antibiotics based on physicochemical properties of these compounds.

Bacteria vs. antibiotics – Bridging infection modeling in *Danio rerio*

Abstract

Growing inefficiency of antimicrobial compounds due to increasingly emerging antibiotic resistance has the potential to become one of the most serious challenges in modern medical practice. Due to poor biodistribution and pharmacokinetic properties *in vitro* test often do not mirror the efficiency of antibiotic compounds *in vivo*. A significant contributor to the low number of newly introduced antibiotic compounds is high costs of animal trials. This study presents the generation and evaluation of a novel bridging, animal infection model using zebrafish embryos. Zebrafish embryos were chosen due to their transparency, allowing fluorescence-based methods to assess the progression of the infection. The investigation included different doses of bacteria, different sites of injection, different temperatures and the antibiotics ceftriaxone and tobramycin. The resulting model is tunable to a certain degree and allows to discriminate between different antibiotic interventions and can thereby be used as a valuable screening tool for novel antibiotic compounds.

Introduction

Salmonella is the leading cause of bloodstream infections in low- and middle-income countries and costs millions of lives each year across the globe every year.[1] Based on epidemiological data it represent a major health burden. Salmonella enterica spp. are extremely versatile and can infect different hosts. Moreover, Salmonella can survive and even replicate intracellularly within Salmonella containing vacuoles (SCV) in many cellular types including macrophages.[2] This information is especially problematic because a number of regularly used antibiotics is unable to cross cell membranes and therefore cannot reach their site of action (i.e. within macrophages).[3] After termination of the antibiotic intervention, these persistent intracellular pathogens can reemerge and lead to a fatal reinfection of the organism. Another serious problem is the growing development of antibiotic resistance (ABR) towards a large number the currently used antibiotics.[4] This phenomenon in combination with a very limited number of novel antibiotic compounds introduced into medical practice [5], [6] is a serious concern and burden for healthcare systems. It is even hypothesized that these developments could lead to a post-antibiotic era in which bacterial infectious diseases could reemerge as one of the leading causes of death like in the pre-antibiotic era.[6]–[8] Consequently, there is an urgent need for novel antibiotics or treatment regimens to avoid such a scenario. However, the development of antibiotics is expensive, however return of investment is relatively small, as efficient antibiotics rarely do get used in the end.[9] In addition to *in vitro* testing, novel antibiotics need to prove effectiveness in expensive *in vivo* trials. To reduce the costs of development of novel antibiotic compounds or treatment regimens and to increase the throughput of compound screenings, the zebrafish embryo animal model is suggested here as a viable alternative to costly rodent animal trials. Due to its unique properties, the zebrafish embryo animal model was already proposed as an early-stage screening tool to study the circulation behavior and macrophage clearance of nanoparticulate drug delivery systems.[10]–[12] The

zebrafish embryo animal model allows for fluorescence-based imaging (confocal) due to its transparency and for high throughput due to its high reproduction rate. Moreover, zebrafish embryos are classified as cell culture trials up to 5 days post-fertilization, thereby avoiding the administrative efforts associated with animal trials.[13] Furthermore, besides qualitative data from confocal imaging, survival analysis allows for quantification of the observed effects. It was therefore the aim of the present study to generate a zebrafish embryo infection model and to evaluate it as potential screening tool for antibiotic compounds

Results and Discussion

In order to develop and verify a *Salmonella* infection model in zebrafish embryos, the first important question to be answered was the number of colony-forming units (CFU) that need to be injected. A series of 30.000, 20.000, 10.000, 7.500, 5.000, 3.000, and 1.500 CFU were injected into zebrafish embryos and the fish were kept at 28°C.

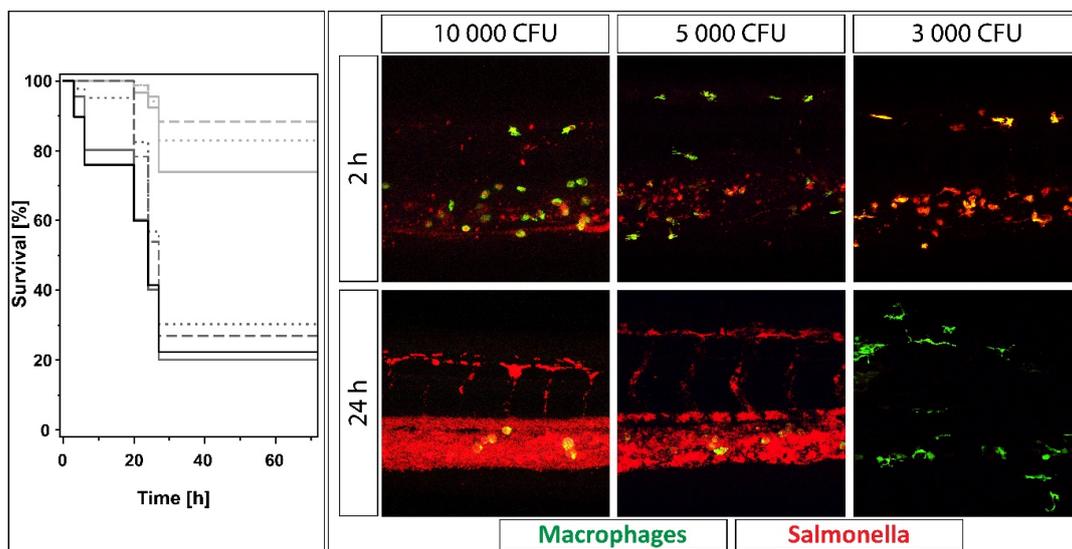

Figure 1: Evaluation of the dose of injected bacteria. The confocal images on the right side show representative images of different doses of bacteria after 2 and 24 h. While the fish survive a dose of 3.000 CFU, higher doses are associated with massive replication of bacteria within the vasculature after 24 h. The Kaplan-Meier survival plot on the left side shows the survival of zebrafish treated with different doses of bacteria. Light grey dotted line: 1.500 CFU, light grey dashed line: 3.000 CFU, light grey solid line: 5.000 CFU, dark grey dotted line: 7.500 CFU, dark grey dashed line: 10.000 CFU, dark grey solid line: 20.000 CFU, black solid line: 30.000 CFU. While 1.500 CFU, 3.000 CFU, and to a certain extent 5.000 CFU are still well tolerated, higher doses are associated with rapid death of fish. The survival analysis showed a dose-dependency.

At low dose low-dose injections (3.000 CFU, but also 1.500 CFU) *Salmonella* were still easily detectable within the whole zebrafish embryo using confocal imaging (Figure 1; An overview of the zebrafish and the location where imaging was carried out is provided by Supplementary Figure S1) Especially after

2 h and in the low CFU settings, most macrophages were infected with Salmonella as indicated by the fluorescence colocalization of the green (GFP of the macrophages) and the red (mCherry of Salmonella) dye, resulting in yellow color. Salmonella were efficiently cleared from the circulation by the zebrafish innate immune system and only present in macrophages after 24 h at a dose of 3.000 CFU. Furthermore, there was a clear dose-dependency of the survival. Doses higher than 5.000 CFU lead to rapid death of fish within 24 h. However, such high doses might not properly reflect the situation *in vivo*. Therefore, the next experiments were carried out at 28°C and with 1.500 CFU injected. The next question was whether it is possible to increase the number of infected macrophages and reduce the number of bacteria in circulation compared to the previous trials using different injection sites, such as the neural tube (a zebrafish embryo scheme depicting the injection sites is provided by Supplementary Figure S2). In order to study the intracellular infection, the vasculature of the fish should ideally be free of bacteria and all the bacteria present only in the macrophages. This way, the influence of bacteria replication within the vasculature on the survival of zebrafish embryos can be minimized and the influence of bacteria replication within macrophages can be maximized.

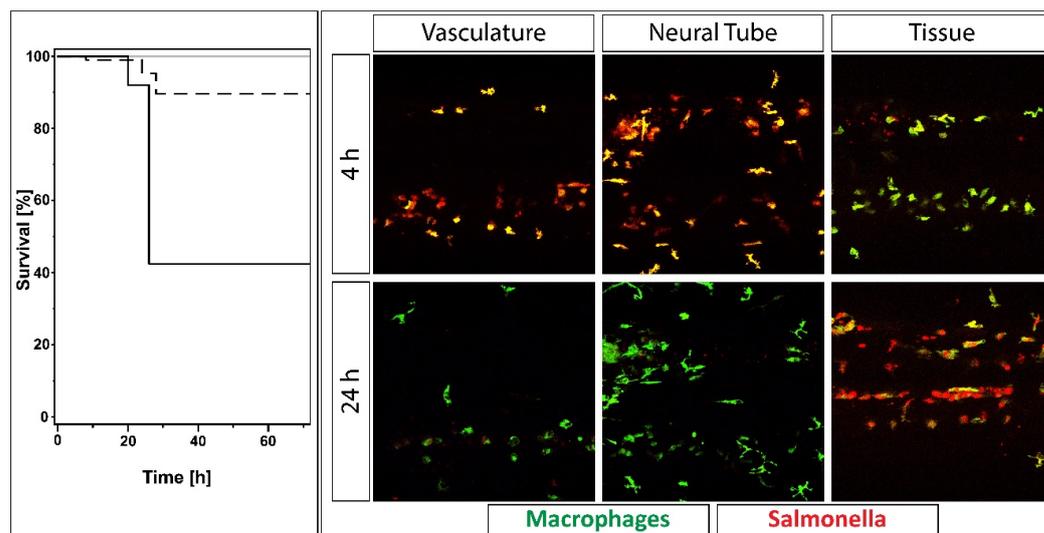

Figure 2: Site of injection evaluation. The figure shows representative confocal images and the survival analysis for the three injection sites (Vasculature refers to the Duct of Cuvier). A fluorescence colocalization of the green (GFP, macrophages) and red (mCherry, Salmonella) is indicated by yellow color. Predominant accumulation of bacteria within macrophages was observed with the neural tube injection and vasculature injection while. Neural tube injection was associated with complete survival while tissue injection showed the lowest survival which is reflected by confocal imaging. The survival plot on the left side shows the survival following neural tube injection (solid light grey line), vasculature injection (dashed black line), and tissue injection (solid black line).

The evaluation of the site of injection showed that injections into the neural tube led to almost exclusive accumulation of bacteria in tissue macrophages whereas the difference between tissue injection and vasculature (Duct of Cuvier) injection was only minor (Figure 2.) However, with respect to survival,

zebrafish subjected to neural tube injection showed complete survival. This leaves no space for improvement. Therefore, and because neural tube injection is very delicate and difficult to reproduce, the neural tube injection was discarded. Similarly to neural tube injection, because tissue injection is hardly reproducible and has the potential for severe injury of the zebrafish while offering no clear benefit, further experiments were carried out using vasculature injection. We observed that bacterial replication was hampered when fish were kept at 28°C. Optimally fish would be kept at 37°C, however at this temperature all fish died. 35°C was therefore selected as a bridging temperature to allow both fish survival and bacterial growth. The results of this trial showed that the injected dose needs to be massively reduced due to the accelerated replication of bacteria at this temperature compared to 28°C.

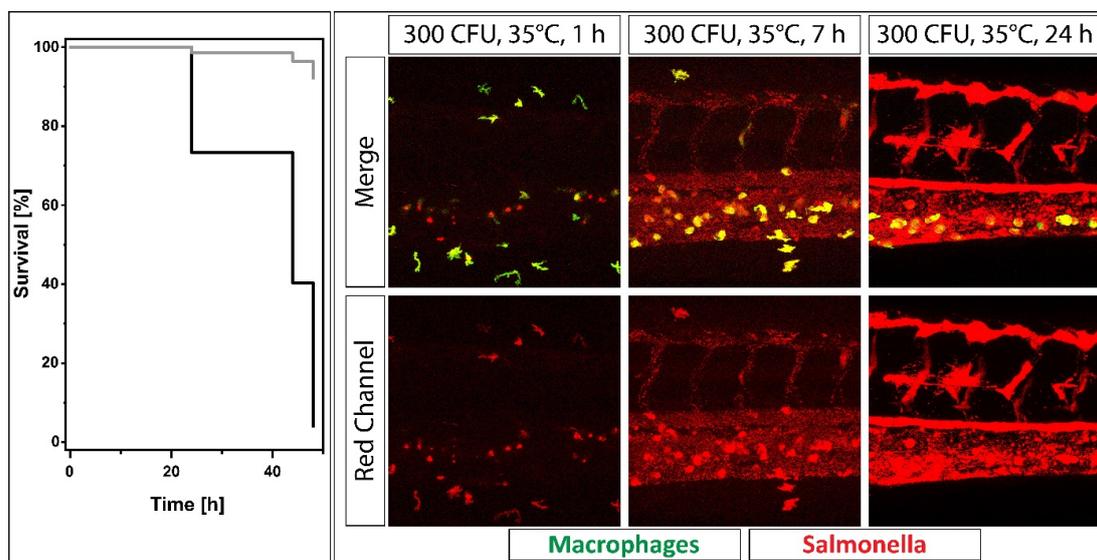

Figure 3: Temperature evaluation. The figure shows confocal images (right) and the survival analysis (upper left) of zebrafish embryos injected with 300 CFU and maintained at 35°C. Despite the lower dose injected into zebrafish embryos, Salmonella replication is accelerated due to the higher temperature. Consequently, images taken after 24 h are similar for 300 CFU at 35°C and 5.000 - 10.000 CFU at 28°C. Moreover, survival analysis showed a lower survival at 35°C (solid black line) compared to zebrafish maintained at 28°C (solid grey line), which reflects the observations during confocal imaging well.

The results of the temperature evaluation showed that zebrafish embryos survive well at 35°C but that the injected dose needs to be massively reduced (Figure 3). In order not to kill the majority of zebrafish embryos within the first few hours, the injected dose had to be reduced to 300 CFU (as compared to 3000 or 1500 CFU at 28°C). At 35°C, confocal images taken after 24 h were very similar to images taken at the same time with 3.000 CFU at 28°C. However, it is important to note that at 35°C the development of zebrafish embryos or larvae is visibly accelerated. Therefore, further experiments were terminated after a maximum of 48 h to avoid conflicts with the animal trial regulations. After establishment of the model parameters, the validation of the model was carried out using the two antibiotics ceftriaxone and tobramycin. Ceftriaxone ($\log P = -1.7$ [14]) exhibits a higher membrane

permeability[15] than tobramycin ($\log P = -5.8$ [16]). Consequently, treatment with ceftriaxone is expected to eradicate all bacteria whereas treatment with tobramycin is expected not to kill bacteria persistent within macrophages. The results of the ceftriaxone and tobramycin trials are displayed in Figure 4.

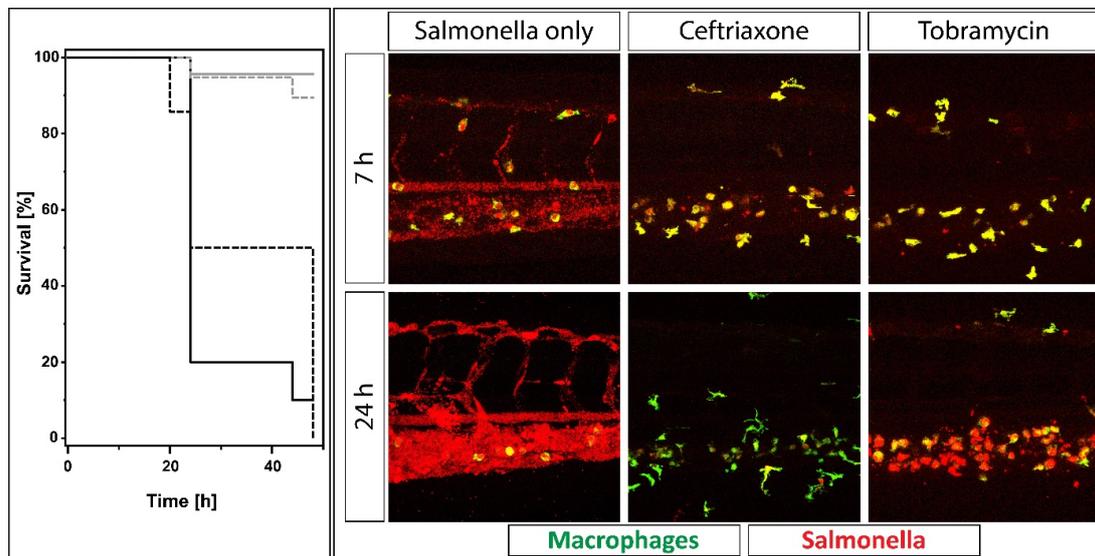

Figure 4: Treatment of Salmonella infection with ceftriaxone or tobramycin. The figure shows confocal images (right side) of Salmonella infected zebrafish (300 CFU) treated with either ceftriaxone or tobramycin (both 600 $\mu\text{g}/\text{zebrafish}$). Confocal imaging allows for a qualitative and survival analysis (left) for a quantitative assessment. Solid light grey line: Untreated zebrafish; Dashed dark grey line: Ceftriaxone; Dashed black line: Tobramycin; Solid black line: Salmonella only. Ceftriaxone was highly efficient in bacteria eradication with almost 100% survival at 24h. Furthermore, bacteria in circulation were almost completely eradicated. Tobramycin on the other hand was unable to eradicate bacteria in circulation and macrophages, leading to a survival of around 50% after 24 h.

The results of the validation trials were able to reflect the different permeabilities of the two antibiotic compounds. While ceftriaxone-treated zebrafish showed a high survival and almost no residual bacteria in circulation or macrophages, tobramycin-treated zebrafish showed a much lower survival of around 50% after 24 h and confocal imaging revealed that the fish were still infected with a large number of bacteria. Moreover, large red dots indicate Salmonella replication within macrophages followed by a burst of the macrophages and subsequent reemergence of Salmonella infection in the vasculature. The presented zebrafish animal infection model is capable of discrimination between the two different antibiotics. Moreover, during this study, Salmonella infections of zebrafish were highly reproducible. Conclusively, the presented model is suitable for testing of novel antibiotic compounds and can be a valuable alternative screening tool for preselection of promising candidates prior to expensive trials in higher vertebrate species.

Conclusion

Growing emergence of antibiotic resistance has the potential to become one of the major burdens for healthcare systems in the 21st century. The search for novel antibiotics is expensive and revenues are at risk to be further reduced due to increasingly strict regulations. A large contributor to high costs are expensive animal trials. We successfully developed a zebrafish animal infection model for the evaluation of novel antibiotic compounds. The zebrafish embryo is an inexpensive animal model that allows for high-throughput screening and fluorescence-based evaluation. We therefore believe that the presented model can be a valuable tool in basic research for novel antibiotic compounds, antibiotic adjuvants, or treatment regimens.

Materials and Methods

Zebrafish embryos (*Danio rerio*) were obtained from adult Tg(mpeg1:Gal4;UAS:Kaede)[17], [18] fish and were kept at 28°C in zebrafish culture medium supplemented with 1-phenyl-2-thiourea (PTU). Fish were kept in accordance with Swiss animal welfare regulations. 2 days post-fertilization (dpf) zebrafish embryos were dechorionized and injected with indicated amounts of the Salmonella strain SDB15 expressing mCherry. After indicated timepoints, infected zebrafish embryos were injected with indicated amounts of antibiotics, or adjuvant where applicable. Zebrafish were then kept at 35°C and at indicated timepoints, zebrafish were imaged using confocal microscopy and the survival was counted. The presence of heartbeat was chosen as the survival criterion. Zebrafish were injected in the Duct of Cuvier (if not stated differently) using a micromanipulator (Wagner Instrumentenbau KG, Schöffengrund, Germany), a pneumatic PicoPump PV830 (WPI, Sarasota, Florida), and a Leica S8APO microscope (Leica, Wetzlar, Germany). Confocal microscopy was carried out using a LEICA POINT SCANNING CONFOCAL “SP5-II-MATRIX“ (Leica, Wetzlar, Germany) equipped with a 25x HCX IRAPO L (NA 0.95) objective. Image analysis was carried out using Fiji ImageJ v. 1.52n. A minimum of three zebrafish embryos were imaged in all settings. Survival analysis was carried out using OriginPro 2018 (64-bit) SR1 b9.5.1.195 (Academic) Software (OriginLab Corporation, Northampton, MA, USA). A minimum of 15-20 zebrafish embryos were used for survival analysis.

Manuscript submitted to PLOS One

Highlights: Emergence of antibiotic resistance in pathogenic bacteria is a severe problem. Many attempts have been made to overcome the widespread development of antibiotic resistances. The two most promising approaches include the search for novel antibiotic compounds and the search for substances that potentiate the effect of already existing antibiotics (antibiotic adjuvants). In this study, we investigated the potential use of 4-hexylresorcinol (4-HR), an alkylresorcinol, as antibiotic adjuvant to improve the effect of various antibiotics against a selection of microorganisms. We could demonstrate that 4-HR significantly reduced minimum inhibitory concentrations (MICs) of various antibiotics. The combination of 4-HR and antibiotics even reestablished susceptibility of bacteria to antibiotics against which they had already acquired antibiotic resistance and was highly efficient in eradication of persister cells. Moreover, *in vivo* experiments in mice showed high cure rates and even complete sanitation (absence of pathogenic microorganisms) of test animals in 75% of all cases.

Abstract

Ever decreasing efficiency of antibiotic treatment due to growing antibiotic resistance of pathogenic bacteria is a critical issue in clinical practice. The two generally accepted major approaches to this problem are the search for new antibiotics and the development of antibiotic adjuvants to enhance the antimicrobial activity of known compounds. It was therefore the aim of the present study to test whether alkylresorcinols, a class of phenolic lipids, can be used as adjuvants to potentiate the effect of various classes of antibiotics. Alkylresorcinols were combined with 12 clinically used antibiotics. Growth-inhibiting activity against a broad range of pro- and eukaryotic microorganisms was determined. Test organisms did comprise 10 bacterial and 2 fungal collection strains, including *E. coli* and *S. aureus*, and clinical isolates of *K. pneumoniae*. The highest adjuvant activity was observed in the case of 4-hexylresorcinol (4-HR), a natural compound found in plants with antimicrobial activity. 50% of the minimal inhibitory concentration (MIC) of 4-HR caused an up to 50-fold decrease in the MIC of antibiotics of various classes. Application of 4-HR as an adjuvant revealed its efficiency against germination of bacterial dormant forms (spores) and prevented formation of antibiotic-tolerant persister cells. Using an *in vivo* mouse model of *K. pneumoniae*-induced sepsis, we could demonstrate that the combination of 4-HR and polymyxin was highly effective. 75% of animals were free of infection after treatment as compared to none of the animals receiving the antibiotic alone. We conclude that alkylresorcinols such as 4-HR can be used as an adjuvant to increase the efficiency of several known antibiotics. We suggest that by this approach the risk for development of genetically determined antibiotic resistance can be minimized due to the multimodal mode of action of 4-HR.

Introduction

Growing inefficiency of known medical preparations due to antibiotic resistance (ABR) of pathogenic microorganisms is a serious problem. [1] Mechanisms of ABR and approaches to minimize (or prevent) these phenomena are therefore a focus of basic research in antibiotic therapy.

ABR may emerge as a result of mutagenesis with subsequent inheritance of genetic determinants, or acquisition of antibiotic resistance determinants via lateral transfer between microorganisms. Overcoming ABR is an important albeit difficult task. [2] Historically, research on suppression of antibiotic resistance and enhancement of the efficiency of antibiotic treatment mainly focused on the search for new antibiotics. However, the number of new antibiotics introduced into medical practice is quite low, with only two new antibiotics registered during the 2000-2013 period. [3] Development of new drug products by combining established or new antibiotics may partially compensate for this insufficient introduction of new compounds. Such combinations may consist of antibiotic hybrids [4] or combinations of two or more antimicrobial agents with different targets in microbial cells to exploit synergistic effects. [5] Alternatively, the effect of an antibiotics can be enhanced by concomitant interference with mechanisms of bacterial resistance. For example, clavulanic acid inhibits beta-lactamases, the enzymes degrading beta-lactam antibiotics, and thus increases the effect of the latter. [6, 7] Substances such as clavulanic acid are adjuvants. They have *per se* no (or only a limited) antibacterial activity but they nevertheless potentiate the effect of antibiotics. [8–11]

Another mechanism of therapy evasion consists of emergence of a small subpopulation of nondividing persister cells in a growing microbial population. [12–18] Persister cells are by definition insensitive (tolerant) to antibiotics. Such cells survive an antimicrobial intervention, germinate after termination of the treatment, and form a new population of antibiotic-sensitive cells. They will have similar properties as the original population and are similarly capable of forming persister cells again. [12–15, 18] The phenotypic transition from a vegetative to a persistent state is associated with development of stress responses and mutations due to low-accuracy repair of damaged DNA. It should be noted that in the case of resistance-related mutations, this may lead to emergence of genetically determined (inherited) ABR. [19] More recently, approaches to minimize the formation of persister cells or to prevent germination were introduced. [8, 20–22] Persisters may be targeted by antibiotics or combined antimicrobial preparations either at the stage of their formation, in order to minimize their numbers, [23] or at the stage of their germination, in order to sensitize them to the action of antibiotics and to prevent reverse phenotypic transition. For example, quorum-sensing autoinducer AIA-1 potentiates the therapeutic effect of an antibiotic during treatment of experimental murine *Pseudomonas aeruginosa* infection by decreasing the numbers of antibiotic-tolerant persister cells. [23]

It was the aim of the present study to identify novel antibiotic adjuvants to enhance the effect of various classes of antibiotics. Our work was based on two assumptions: decreased metabolic activity in the cells of pathogenic microorganisms caused by an adjuvant will result in suppressed mechanisms of antibiotic resistance and minimization of the number of surviving persister cells (up to their possible elimination). This will decrease the risk of reinfection and the formation of genetic resistance determinants. Alkylresorcinols were identified to have the required properties. These phenolic lipids are secondary metabolites of plants and can as well be found in some microorganisms. [24] They have a weak antimicrobial activity. 4-hexylresorcinol (4-HR) (Fig 1) is a synthetic derivative used as topical drug in antibacterial oral gargles and throat lozenges. [25] Recently, an incorporation of 4-HR within PLGA polymer composite films was proposed as a strategy to obtain biomedical and packaging products with

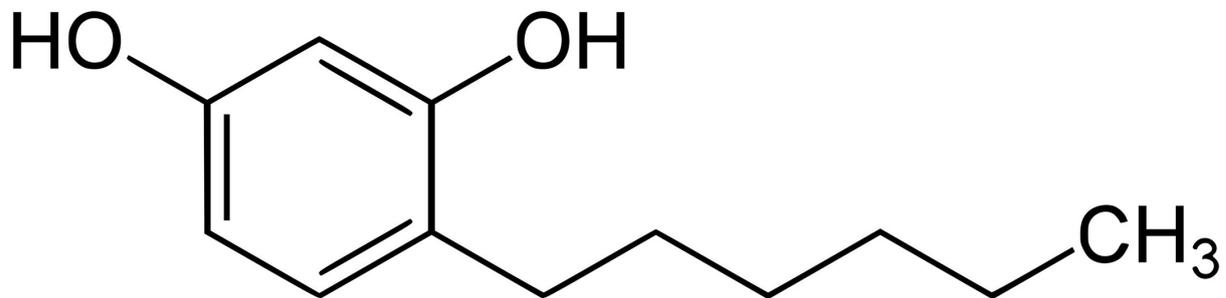

Fig 1. Chemical structure of 4-hexylresorcinol (4-HR). 4-hexylbenzene-1,3-diol has a molecular weight of 194.27 g/mol, a solubility in water of 800 mg/L, and an octanol-water partition coefficient of 3.9.

<https://doi.org/10.1371/journal.pone.0239147.g001>

antimicrobial properties. [25] In food industry, 4-HR is frequently used as a preservative and to prevent browning. [26] The widespread use in food industry and the antiseptic activity of 4-HR give rise to the assumption that 4-HR might be a safe adjuvant for antibiotic combination therapies.

Materials and methods

Alkylresorcinols

4-hexylresorcinol (Fig 1) was purchased from Sigma- Aldrich (St. Louis, MO, USA) while other alkylresorcinols were provided by Carboshale Ltd. (Virumaa, Estonia). Phenolic lipids were added as stock solutions in ethanol (3% vol/vol) or dimethyl-sulfoxide (DMSO) (3% vol/vol).

Microorganisms

Nonpathogenic strains of pathogenic microorganisms such as gram negative *E. coli* K12 and gram positive *S. aureus* 209P were obtained from the fungal and bacterial collection of the All-Russian Collection of Microorganisms (Pushchino, Moscow Region, Russian Federation, see Table 1). For the checkerboard method and the *in vivo* experiments, the following strains from the collection of the Research Institute on Infant Infections (St. Petersburg, Russia) were

Table 1. Effect of 4-hexylresorcinol (4-HR) on a selection of various microorganisms. MIC values are means of two series of experiments.

Classification	Microorganism	Strain No.	MIC (mg/L)
Prokaryota (Gram positive)	<i>Bacillus subtilis</i>	VKM-B436	20
Prokaryota (Gram positive)	<i>Lactococcus lactis</i>	B-1662	20
Prokaryota (Gram positive)	<i>Micrococcus luteus</i>	VKM-Ac2230	20
Prokaryota (Gram positive)	<i>Streptococcus faecalis</i>	B-602	20
Prokaryota (Gram positive)	<i>Staphylococcus aureus</i>	209P	25

used: *Staphylococcus aureus* ATCC 29213 (reference strain) and isolates MRSA *S. aureus* (SA0077, SA0206, SA0411 SA0318); clinical isolates *Enterococcus faecalis* E23 and E28; *Escherichia coli* ATCC 25922 (reference strain) and *Escherichia coli* isolates (1273, 1263); clinical isolates of *Klebsiella pneumoniae* (1191, 204, 895); *Pseudomonas aeruginosa* (1215, 56); *Acinetobacter baumannii* (121, 1308); as well as clinical isolate *Klebsiella pneumoniae* KPM9 from the collection of the State Research Center for Applied Microbiology and Biotechnology (Obolensk, Russia). Bacterial cultures were grown in LB medium for 18–20 hours. Fungal cultures were grown in wort medium for 36 hours (to the stationary growth phase). Second cycle cultures were inoculated and grown for 1 hour to the early exponential phase in 250 mL flasks with 50 mL of LB medium. Samples were dispensed (2 mL) into glass test tubes containing the indicated amounts of antibiotics and adjuvants (phenolic lipids). Starting concentration was 5×10^5 cells/mL. The test tubes were incubated for 24 hours at 30°C on a rotary shaker (100 rpm) to determine the minimal growth-inhibiting concentrations (MIC) of saprophytic organisms or non-pathogenic strains of bacteria (Table 1). Bacterial growth was assessed spectrophotometrically by OD₆₀₀ measurements on a Jenway Spectrophotometer 7315 (Jenway, Staffordshire, UK).

Determination of antibacterial activity of alkylresorcinols

The tested antibiotics are listed in S1 Table. The degree of prolongation of alkylresorcinol bactericidal action was determined by the use of a mixed culture of gram positive *B. subtilis*, gram negative *P. fluorescens*, and yeasts *S. cerevisiae*. Individual cultures were grown to the stationary phase and mixed in equal amounts to prepare the inoculum. The inoculum (5% vol/vol) was added to the medium consisting of a mixture (1:1) of LB medium and wort. Flasks were incubated and bacterial growth was assessed spectrophotometrically as described above.

Minimal growth-inhibiting concentrations (MIC)

Antibiotics were characterized by their minimal growth-inhibiting concentrations (MIC), which were determined for every test organism using conventional serial dilution in liquid media followed by plating. Phenolic lipids were used at concentrations of $\frac{1}{2}$ MIC; the latter was determined for each test organism. The criteria for adjuvant efficiency were as follows: decreased MIC of a given antibiotic in combination with AR ($\frac{1}{2}$ MIC), which was determined as the absence of growth of a test organism after 24 hour incubation in liquid medium; decreased number of viable persister cells (colony-forming units, CFU) retaining viability after 24 hour incubation at high antibiotic concentration (10 MIC and above, by [27]). CFU numbers were determined by plating serial ten-fold dilutions on agar (1.5%) LB medium. All values represent means of three independent sets of experiments with three repetitions each.

Chequerboard method

Stock solutions of the tested antibiotics were prepared to obtain two-fold serial dilutions in vertical rows 1–8 of a 96-well plate. 4-HR stock solutions were prepared to cover final concentrations of 8 to 512 µg/mL. 0.1 mL of antibiotic and/or 4-HR solution in broth (or broth only) was added to a well, then 0.1 mL of bacteria suspension was added to a final concentration of 5×10^5 cells/mL. Cultivation temperature was 35–37°C. Results were assessed by measuring bacterial growth in the vertical and horizontal rows. MIC was defined as the minimal concentration at which bacterial growth was absent. The type of interaction of antibiotics (AB) and

4-HR was calculated using the FICI coefficient (Eq 1) as recommended: [28]

$$FICI = \frac{MIC(AB + 4 - HR)}{MIC(AB)} + \frac{MIC(AB + 4 - HR)}{MIC(4 - HR)} \quad (1)$$

Apart from the recommended coefficients, one more was introduced (K1), showing the MIC decrease for the monopreparation compared to the binary one:

$$K1 = \frac{MIC(AB)}{MIC(AB + 4 - HR)} \quad (2)$$

With K1 reflecting the decrease in the effective dose of antibiotic in the presence of an ineffective concentration of 4-HR.

***K. pneumoniae* KPM9 induced experimental sepsis**

Outbred female white mice (18–21 g; Andreevka Farm, Scientific Center for Biomedical Technologies, Russia) were infected intraperitoneally by *K. pneumoniae* (clinical isolate KPM9) cell suspensions (0.5 mL, $50 \times LD_{50}$). The LD_{50} value was calculated according to Cerber in the modification by Ashmarin and Vorov'ev [29] according to survival duration after infection. The average LD_{50} values for *K. pneumoniae* KPM9 were 21 cells.

Mice were treated with polymyxin B (Pm; Bharat Sirams and Vaksins Ltd., India) and/or 4-HR. The doses were calculated as recommended. [29, 30] Treatment began 24 hours after infection (day 0). Pm was administered intramuscularly. 4-HR was administered *per os* twice a day for five days as a solution in 50% ethanol using an oral gavage needle (0.2 mL). Mice were monitored for 14 days. Criteria of treatment efficiency were survival and contamination of internal organs with bacteria (S3 Table). Severity of the infection was assessed using the overall condition of the animals (behavior, mobility, appetite, weight, and lymph node size). Surviving animals were euthanized, and bacteriological and postmortem study of their organs was carried out, including plating of the lungs, spleen, and blood samples onto solid HRM medium followed by a 48 hour incubation at 37°C.

Laboratory animal welfare

Animals were kept under standard conditions according to guidelines of the US National Institutes of Health (NIH Publication No. 8023, revised 1978). Mice had free access to water and food (Laboratorkorm, Moscow, Russia) and were kept in polycarbonate cages (LabProducts, Seaford, DE) in groups of up to 10 animals. Animal health and behavior was monitored twice daily. Animals were handled by animal caretakers, which were trained in accordance to protocols established by the USAMRIID, WRIAR and UHSUS. Animal experiments were approved by the Bioethics Commission, State Research Center for Applied Microbiology & Biotechnology. Animal experiments involved fast spreading mice sepsis with a lethality of 100% without treatment within 5 days. Surviving animals were euthanized after 14 days. There is no alternative to these experiments since only an animal experiment can model all aspects of the bacterial infection [31, 32]. Studies were designed to measure survival percentages. In view of the severity and rapid progression of the infection, animals were bound to die from the disease. This provides a very small window of opportunity to intervene and to decide whether animals have reached a humane end point and should be euthanized. The number of animals was 60, 25 of which were found dead and 35 were euthanized.

Results

Antimicrobial activity of alkylresorcinols and phenolic lipids

Based on the hypothesis that phenolic lipids (Figs 1 and 2) can be used as adjuvants for antibiotic therapy, screening experiments were performed to study their impact on bacterial growth (MIC determinations) and subsequently synergistic effects with different classes of antibiotics (S1 Table). The MIC of phenolic lipid preparations were determined using as test organisms *S. aureus* 209P (a nonpathogenic *S. aureus* strain) and *M. smegmatis* AC-1239 (a nonpathogenic

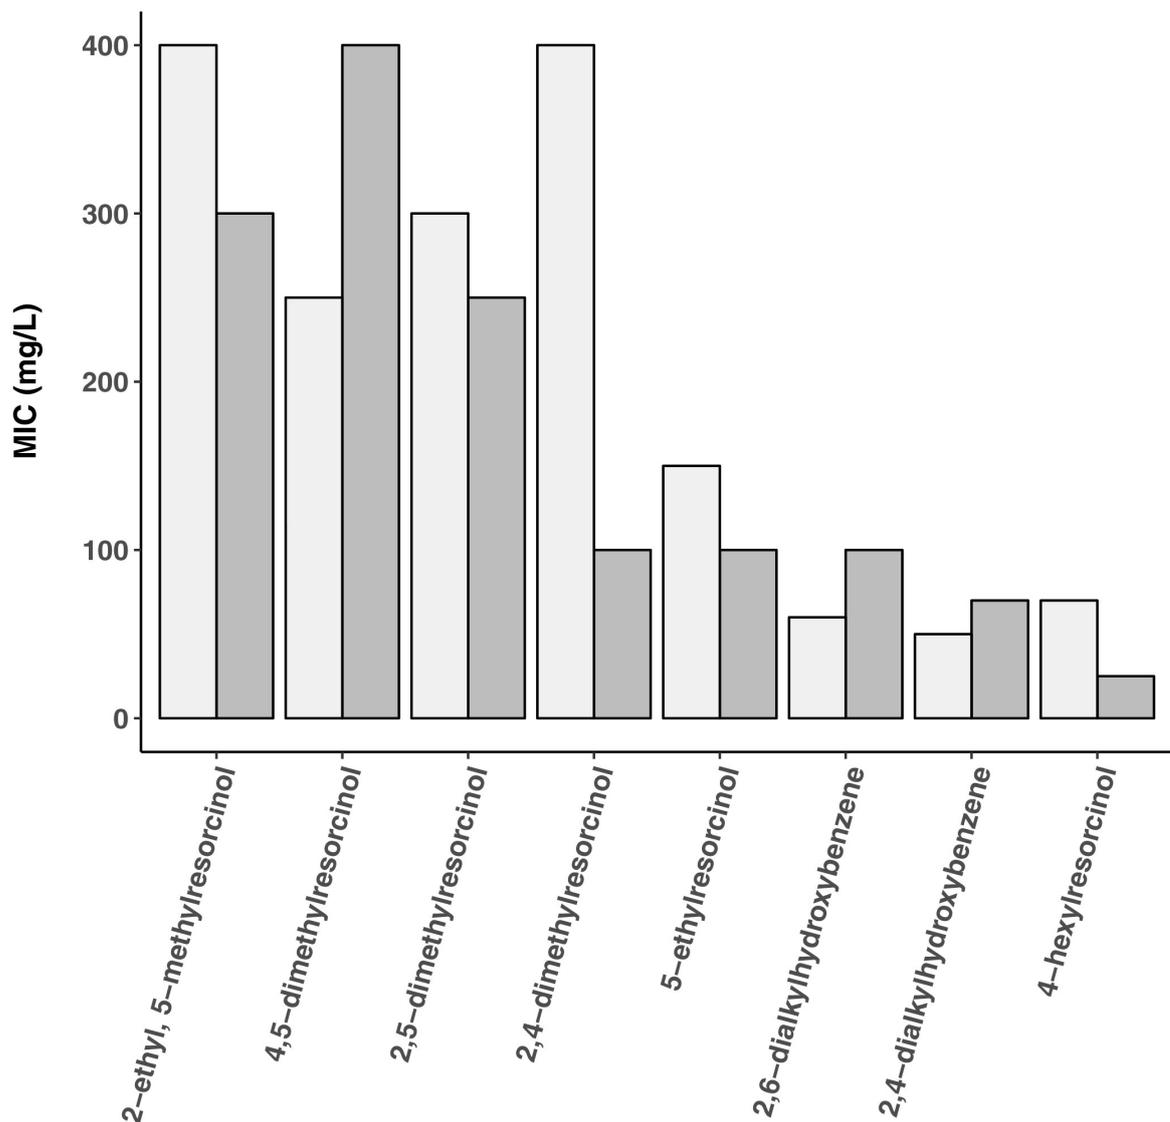

Fig 2. Minimal growth-inhibiting concentrations (MIC) of alkylresorcinols. 5-methylresorcinol showed poor activity against *M. smegmatis* (MIC = 300 mg/L, light grey bars) and *S. aureus* (MIC >5000 mg/L, dark grey bars). Values are means of two independent series of screening experiments.

<https://doi.org/10.1371/journal.pone.0239147.g002>

analog of the pathogen *M. tuberculosis*) (Fig 2). Different types of alkylresorcinols, amphiphilic 2,4- and 2,6-dialkylhydroxybenzenes and the more hydrophobic 4-hexylresorcinol (4-HR) were tested. In view of the high activity of 4-HR, its antimicrobial activity was subsequently studied using a broad range of microorganisms (Table 1). Gram positive bacteria were found to be most sensitive to 4-HR, with MICs of 20-50 mg/L. *M. smegmatis* was characterized by a MIC of 70 mg/L. Gram negative bacteria, yeasts and fungi were less sensitive.

Effect of 4-hexylresorcinol as antibiotic adjuvant

In the next series of experiments, MIC was determined for each antibiotic supplemented with 4-HR at the concentration of $\frac{1}{2}$ MIC, which was insignificant for preventing growth of the test organisms, but suppressed their metabolic activity. The results are presented in Tables 2 and 3. In the case of *S.aureus* 209P, the presence of 4-HR ($\frac{1}{2}$ MIC) enhanced the antimicrobial action of all tested antibiotics, especially of polymyxin, vancomycin, capremabol, levomycetin, and ampicillin (5- to 10-fold increase). In the case of *E. coli* K12, a significant intensification of the antimicrobial action was as well observed in presence of 4-HR ($\frac{1}{2}$ MIC). 4-HR had the greatest effect on activity of polymyxin, gentamicin, azithromycin, and levomycetin (MIC decreased 10- to 50-fold). The lowest effect (2- to 3-fold) was observed for cyclosporine, vancomycin, and rubomycin. In the case of a yeast-like organism (i.e. *C. utilis*), two antibiotics were tested:

Table 2. MIC of various antibiotics against gram positive *S. aureus*. MIC of antibiotics alone or antibiotics combined with 15 mg/L 4-HR corresponding to $\frac{1}{2}$ MIC are shown. Values are means of two series of experiments.

Antibiotic	MIC antibiotic ($\mu\text{g/L}$)	Fold decrease of MIC in presence of 4-HR
Capremabol	40	10
Ampicillin	0.25	5
Vancomycin	0.5	5
Levomycetin	2.5	5
Polymyxin	10	5
Gentamicin	0.2	4
Doxycycline	0.4	4
Rubomycin	200	4
Ciprofloxacin	3	3

<https://doi.org/10.1371/journal.pone.0239147.t002>

Table 3. MIC of various antibiotics against gram negative *E.coli*. MIC of antibiotics alone or antibiotics combined with 100 mg/L 4-HR corresponding to $\frac{1}{2}$ MIC are shown. Values are means of two series of experiments.

Antibiotic	MIC antibiotic ($\mu\text{g/L}$)	Fold decrease of MIC in presence of 4-HR
Polymyxin	5	50
Gentamicin	1	10
Azithromycin	1	10
Levomycetin	12.5	10
Ciprofloxacin	0.75	5
Doxycycline	5	5
Capremabol	100	5
Ampicillin	40	4
Tobramycin	60	4
Rubomycin	300	3
Vancomycin	200	2

<https://doi.org/10.1371/journal.pone.0239147.t003>

ciprofloxacin and naftifine hydrochloride. However, their MIC decreased insignificantly in presence of 4-HR. Antimicrobial action of the studied antibiotics against both tested bacteria increased in the presence of $\frac{1}{2}$ MIC of 4-heptylresorcinol leading to similar albeit weaker effects as observed with 4-HR. In view of the higher potency of 4-HR, only this compound was used for the next series of experiments.

Effect of 4-hexylresorcinol on germination

Dormant microbial forms lack metabolic activity and therefore targets of many biocidal agents. Moreover, they exhibit high resistance to damaging factors. Suppression of their germination is therefore a challenge. Addition of 4-HR for the indicated period of time to liquid medium prior to inoculation inhibited germination of *B. cereus* spores (Table 4). The decrease in the titer of viable spores (CFU) depended both on 4-HR concentration and exposure duration. We conclude that 4-HR exhibits antimicrobial activity against both bacterial vegetative cells and their dormant forms. Pretreatment of spores impairs their ability to germinate.

Effect of 4-hexylresorcinol on persister cells

4-HR was combined with antibiotics to study the effect of 4-HR on viability of persister cells, i.e. cells remaining viable in the presence of biocidal concentrations of antibiotics [18]. The test strain *E. coli* K12 was treated with ampicillin and ciprofloxacin (antibiotics inhibiting different targets in bacterial cells, i.e. cell wall synthesis and DNA synthesis, respectively). Their concentrations of 60 and 100 $\mu\text{g}/\text{mL}$, respectively, was above their MIC. The results presented in Table 5 demonstrate a decrease in the numbers of surviving persister cell in presence of 4-HR ($\frac{1}{2}$ MIC). No viable cells were found after 2 days (for ampicillin) and 7 days (for ciprofloxacin) if antibiotics were combined with 4-HR. A negligible amount of viable cells (i.e. 32 CFU/ml) was detected after 1 day of incubation with ampicillin in the presence of 4-HR. This is in contrast to incubations with the antibiotics alone, which did not lead to complete eradication of the microorganisms under all tested conditions (viable cell count was $>3 \times 10^3$ CFU/mL).

Effects of 4-HR on clinical isolates of pathogenic bacteria

Synergistic effects of antibiotics and 4-HR were studied using clinical isolates of pathogenic bacteria causing infections associated with medical interventions. The checkerboard method

Table 4. Impact of 4-hexylresorcinol on germination of *B. cereus* spores. Liquid medium containing *B. cereus* B-504 spores was pretreated with 4-HR for the indicated period of time. Germination was in absence (-); 100% control without 4-HR corresponds to $6.0 \pm 1.0 \times 10^7$ CFU/mL or presence (+); 100% control without 4-HR corresponds to $9.5 \pm 0.5 \times 10^7$ CFU/mL of 4-HR. Values are means of two series of experiments.

Treatment	4-HR (mg/L)	% rate of germination
No pretreatment (+)	5	95 \pm 15%
	10	77 \pm 13%
	25	0%
1 hour pretreatment (-)	50	100 \pm 18%
	100	98 \pm 16%
	500	83 \pm 14%
	1000	51 \pm 11%
2 days pretreatment (-)	50	75 \pm 16%
	100	75 \pm 14%
	500	55 \pm 11%
	1000	20 \pm 3%

was applied to calculate a fractional inhibitory concentration index (FICI). [28] FICI values were categorized into three groups: Synergy (FICI \leq 0.5), indifference, or absence of interaction, ($0.5 \leq$ FICI \leq 4.0), and antagonism (FICI \geq 4.0). Additionally, the coefficient K1 was calculated. With this coefficient, the decrease in the effective dose of antibiotic in the presence of 4-HR (K1) can be determined.

For this assessment, clinical isolates of gram positive bacteria (*S. aureus* and *E. faecium*) as well as gram negative bacteria (*E. coli*, *K. pneumoniae*, *A. baumannii*, *P. aeruginosa*) were selected (S2 Table). In 26% of the studied antibiotic with 4-HR combinations, no effect of 4-HR on the MIC of antibiotics was observed. But in the remaining 74%, the MIC of the studied antibiotics decreased 2- to 512-fold, with a fourfold and more pronounced MIC decrease found in 33% of the combinations and an eightfold and more pronounced MIC decrease occurred in 12% of the groups. Importantly, potentiation of antibiotic activity (strong synergistic effects as indicated by the FICI parameter and decrease in their effective doses in combination with 4-HR as indicated by the K1 parameter) was observed for both sensitive and resistant strains. 4-HR exhibited synergism and caused a significant decrease in the MIC of antibiotics in the case of interactions with ciprofloxacin (7 combinations), polymyxin (5 combinations), and amikacin (4 combinations). 4-HR efficiency varied depending on microbial taxa and was higher in the case of gram negative bacteria. 4-HR in combination with polymyxin showed synergism against *A. baumannii*, *P. aeruginosa* and *K. pneumoniae* with different levels of sensitivity. As a representative example, results for clinical isolates of *K. pneumoniae* KPM9 (covering both sensitive and resistant strains) are shown in Table 6. In the case of polymyxin, for example, strong synergistic effects were observed (FICI = 0.07 µg/L) with a 16-fold decrease in the effective dose of antibiotic in the presence of 4-HR.

***In vivo* proof of concept using an experimental mouse sepsis model**

Based on the results of the checkerboard analysis (Table 6), a mouse experimental sepsis model was developed to demonstrate *in vivo* effects of a combination of polymyxin and 4-HR in infections caused by clinical isolates of pathogenic *K. pneumoniae*. For our model of mouse klebsiellosis, ten outbred mice per group were infected by intraperitoneal injection of a culture of antibiotics sensitive *K. pneumoniae* KPM9 (0.5 mL, \approx 50 LD₅₀, 1000 CFU/mouse). Treatment of groups started 24 hours after infection and continued for five days. Since oral polymyxin (Pm) preparations are not well tolerated in mice, Pm was applied as intramuscular injection (1 mg/kg). The 4-HR preparation was administered twice a day *per os* (PO). Total daily 4-HR doses were 30 mg/kg. A representation of the survival data for Pm in combination with 4-HR is shown in Fig 3. On day 14 of the experiment, surviving animals were euthanized. Their spleen, blood, and lungs were examined to determine viable cell titers (CFU) of *K. pneumoniae* by plating serial dilutions on solid media.

Table 6. Assessment of interactions between 4-HR and various groups of antibiotics against clinical isolates of gram negative pathogenic *K. pneumoniae*. The checkerboard method yields FICI values (Eq 1) as well as the coefficient K1 (decrease in the effective dose of antibiotic in the presence of 4-HR; Eq 2). Synergy is defined by $FICI \leq 0.5$, absence of interaction by $0.5 < FICI \leq 4.0$, and antagonism by $FICI \geq 4.0$. For the resistant pathogen, 4-HR concentrations were 512 $\mu\text{g/L}$. For the sensitive strain, 4-HR concentrations were 64 $\mu\text{g/L}$. Unit of MIC is $\mu\text{g/L}$. MIC AB designates MIC of the antibiotic alone.

Antibiotic	Phenotype	MIC AB	K1	FICI
Amikacin	Sensitive	1	1	2
Ampicillin	Sensitive	8	0.25	5
Cefotaxim	Sensitive	0.5	2	1.5
Ciprofloxacin	Sensitive	0.06	4	0.26
Meropenem	Sensitive	0.03	4	0.26
Polymyxin	Sensitive	0.25	16	0.07
Tigecycline	Sensitive	0.12	1	2
Amikacin	Resistant	128	16	0.09
Ampicillin	Resistant	256	0.1	8.06
Cefotaxim	Resistant	128	8	0.25
Ciprofloxacin	Resistant	128	16	0.09
Meropenem	Resistant	16	2	0.56
Tigecycline	Resistant	2	2	0.56

<https://doi.org/10.1371/journal.pone.0239147.t006>

Indications of the *Klebsiella* infection (adynamia, anorexia, and loss of weight) were observed during the experiment and resulted in a decrease in the body mass as well as death of animals. Treatment of animals with the Pm + 4-HR combination showed high efficiency when the 4-HR preparation was administered *per os*. Survival rate in the group treated with Pm + 30 mg/kg/day 4-HR was the highest (80%), while all the mice in the control group died. Moreover, life duration (9 days) of animals treated with Pm + 30 mg/kg/day 4-HR was more than twice that of the control mice (4 days). Approximately 75% of surviving animals in this group were sanitized, as demonstrated by an absence of viable *K. pneumoniae* in inner organs. In the remaining mice, bacterial numbers in the spleen and lungs were approximately 3.2×10^2 and approximately 5.4×10^2 CFU/mL, respectively (S3 Table). No bacteria were found in the blood. Surprisingly, survival rates actually decreased to 60% in groups treated with higher 4-HR doses (i.e. 50 or 75 mg/kg/day). Higher doses of 4-HR did as well reduce the percentage of sanitized mice (40% and 30% of surviving mice treated with 50 and 75 mg/kg/day, respectively). It should be noted that intraperitoneal administration of 4-HR was abandoned since it showed low efficiency and caused pain. Treatment of animals with 1 mg/kg Pm alone did not result in complete recovery of mice: in 40% of surviving animals, inner organs were contaminated with *K. pneumoniae*. None of the surviving animals receiving 4-HR alone were sanitized.

Discussion

Research on microbial growth autoregulation revealed microorganisms (both pro- and eukaryotic) to produce low-molecular mass compounds acting as density regulators, which in a number of bacteria are phenolic lipids of the alkylresorcinol group. [33] Alkylresorcinols were subsequently shown to act as autoinducers of the quorum-dependent regulatory system. [33, 34] This is in agreement with literature confirming this function of alkylresorcinols. [35] At increasing concentrations of alkylresorcinol, population growth of microorganisms is restricted and the development of a hypometabolic and then anabiotic state is induced. [33, 34] This motivated us in the present study to explore a possible role of alkylresorcinols and other phenolic lipids as antibiotic adjuvants.

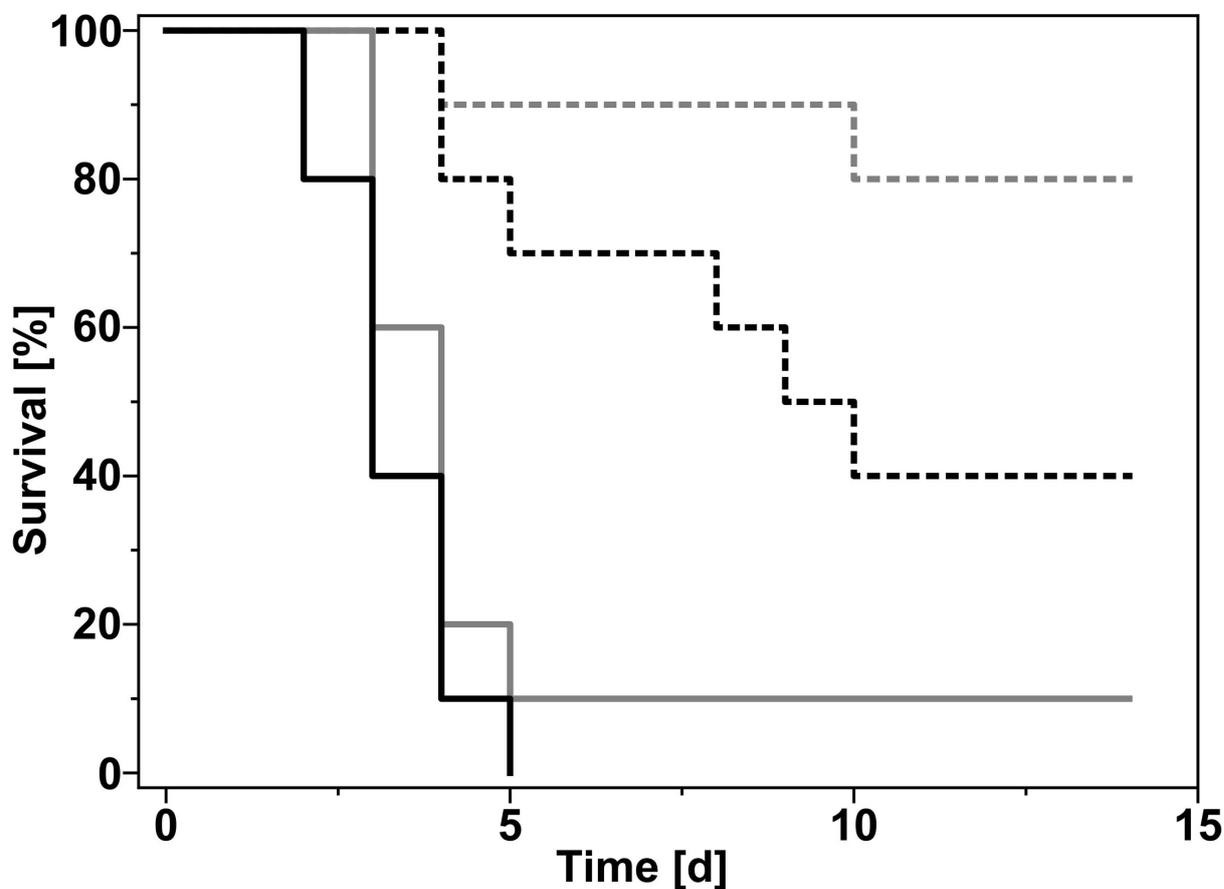

Fig 3. Effect of 4-hexylresorcinol in a mouse bacterial sepsis model. A total of 10 mice per group were infected with *K. pneumoniae* (clinical isolate KPM9; 1000 CFU/mouse). Treatment started 24 hours after infection (day 0). Mice were treated with polymyxin (1 mg/kg, intramuscular) and/or 4-HR (15 mg/kg twice a day for five days, *per os*). Dashed grey line: polymyxin and 4-HR combined. Dashed black line: polymyxin alone. Solid grey line: 4-HR alone. Solid black line: untreated control.

<https://doi.org/10.1371/journal.pone.0239147.g003>

4-HR (4-hexylresorcinol) was identified in screening experiments to have the strongest effects on bacterial growth. In these experiments, antimicrobial activity of alkylresorcinols with methyl-, ethyl-, and hexyl groups was found to increase with increasing hydrophobicity. Comparison of 4-HR and 2-ethyl-5-methylresorcinol revealed that the absence of screening of hydroxyl groups by a large alkyl group was important for antimicrobial activity. Thus, while the more hydrophobic compound 2-ethyl-5-methylresorcinol could have been expected to have higher antimicrobial activity than 4-HR, it was in fact less toxic to the test organisms. Comparison of 2,4- and 2,5-dimethylresorcinols revealed hydroxyl group screening to be less important for *S. aureus* (MIC 100 and 250 mg/L, respectively) than to *M. smegmatis* (400 and 300 mg/L, respectively).

Antimicrobial activity of 4-HR on microorganisms seem to depend on cell wall properties. High sensitivity was associated with a peptidoglycan-based outer cell wall structure of gram positive bacteria. The additional outer lipid membrane of gram negative bacteria, as well as the complex chitin and polysaccharide-based cell wall structure of yeast and fungi, seems to confer

some degree of resistance. High resistance to 4-HR in *M. smegmatis* might be due to the presence of lipid structures and mycolic acids, causing high hydrophobicity of their cell surface. Dependence of antimicrobial activity of phenolic lipids on their hydrophobicity is in agreement with literature, [36] which reports increased antimicrobial activity of n-alkylphenols with increasing length of the alkyl chain and higher resistance of microorganisms with lipid-enriched cell membranes to alkylphenols. Based on these results, 4-HR was selected for further characterization.

The utility of 4-HR as potent adjuvant for the treatment of bacterial infections was demonstrated in combination with several antibiotics. The biocidal effects of these antibiotics to *S. aureus* and *E. coli* were potentiated 5- to 50-fold in the presence of $\frac{1}{2}$ MIC 4-HR. This result opens the opportunity for novel treatment regimens against bacterial infections. For instance, a higher bactericidal effect obtained with the combination of antibiotic and 4-HR could result in lower doses of antibiotics to be applied to a patient while still maintaining the same effectiveness. Consequently, antibiotics that are rarely used in humans due to side effects associated with bactericidal doses (such as polymyxin) might become a viable alternative when combined with 4-HR. In view of the challenges related to antibiotics resistance, this strategy could help to delay the hypothesized post-antibiotics era.

In addition to vegetative forms, bacteria can undergo transformation into a dormant form, leading to the emergence of persister cells. These dormant forms or endospores are characterized by the absence of metabolic activity and therefore possess a high resistance towards environmental insults including radiation, temperature, and chemicals. Previous studies [12, 37–39] suggest that persister cells are responsible for the chronic nature of many bacterial infections and that their formation is induced by prolonged use of antibiotics. [40, 41] This is due to selective pressure on the pathogens promoting persistence. [42, 43] Efficiency of antibiotic therapy can therefore be compromised by the development of antibiotic-resistant clones. Furthermore, persister cells surviving antibiotic treatment may transfer genetic information, e.g. plasmid encoded resistance genes, vertically from parent to offspring or transfer genetic information to another species of bacteria within the same generation by means of transduction, transformation and conjugation (horizontal gene transfer). It is therefore important to eliminate antibiotics-insensitive, dormant persister cells. Based on these considerations, we measured the synergistic effect of a combination therapy using antibiotics-resistant persister cells. It was indeed possible to demonstrate that the addition of 4-HR significantly decreases the number of germinating *B. cereus* spores in liquid medium, as well as on agar medium. This in contrast to treatment with antibiotics alone. The observed effect was dependent on 4-HR concentration and duration of exposure. Moreover, the number of viable spores after prolonged treatment (14 days) was below the limit of detection. Thus, the risk of reemergence of an infection after termination of the antibiotic treatment due to germination of persister cells can be minimized. This result demonstrates that bacterial strains, that already acquired ABR, can become sensitive to the antibiotic compound again when 4-HR is co-administered. It is therefore tempting to speculate that antibiotics, that are rarely used due to widespread resistance towards that antibiotic, can become a viable treatment alternative again.

To systematically study interactions of 4-HR and antibiotics with clinical isolates of pathogenic bacteria, we used the checkerboard method. A FICI parameter of ≤ 0.5 [28] is thereby indicative of synergism. This classification is confirmed if the MIC of the antibiotic decreases at least fourfold in the presence of 4-HR ($K1 \geq 4$). Strong synergism was observed both for gram negative and gram positive bacteria. 4-HR combinations with fluoroquinolones, polymyxin, and amikacin with gram negative bacteria as targets were the most promising variants S2 Table. Interestingly, 4-HR may have both synergistic as well as antagonistic effects. These

results emphasize the importance of FICI values and the coefficient K1, which have to be determined for each new combination of antibiotic, 4-HR and pathogen. Importantly, 4-HR enhanced antibiotic activity equally well in both antibiotic sensitive and resistant bacterial strains.

In vitro efficiency of antibiotics in 4-HR binary compositions was determined for the gram negative bacterium *Klebsiella pneumoniae*, which causes various forms of klebsiellosis infections. Death rate in humans with the generalized klebsiellosis infection may be as high as 60%. Emergence of antibiotic-resistant *K. pneumoniae* strains is a major problem. [44] Therapy of nosocomial infections is often difficult due to high resistance of the causative agents to most known antibiotics, which develops in 30–50% of the patients in the course of monotherapy. Since the virulence of *K. pneumoniae* depends significantly on its ability to form a polysaccharide capsule preventing phagocytosis, the hypermucooid strain *K. pneumoniae* KPM9 was selected for the development of an animal model. *In vitro* results showed a significant effect of 4-HR on antibiotic efficiency with a FICI value of 0.07 and a 16-fold decrease of the polymyxin MIC in combinations with 4-HR (Table 6). In view of these pronounced synergistic effects, we decided to focus for the following series of experiments on combinations of *K. pneumoniae*, polymyxin, and 4-HR. With respect to selection of the antibiotic, it should be noted that previous *in vitro* studies reported synergistic effects of polymyxin with other antibiotics in that bactericidal activity was enhanced and bacterial heteroresistance was suppressed. [45–47] Clinical studies revealed that a combination therapy including polymyxin has a better clinical outcome as compared to a monotherapy. This can be attributed to a decreased risk of Pm associated side effects and offers interesting options with respect to the use of adjuvants such as 4-HR. [48]

Klebsiellosis treatment is often based on an assessment of the activity of preparations in treatment of experimental *Klebsiella* infections in animals. Mice are highly sensitive to this infection. Mouse klebsiellosis is characterized by an acute generalized disease, with *K. pneumoniae* and sepsis in virulent forms. Death due to infection-related toxic shock occurs within a week after infection. Successful antibiotic treatment results in elimination of the infectious agent and normalization of clinical laboratory parameters. In the present study, it was indeed possible to eradicate *K. pneumoniae* in a mouse sepsis model by a combination of polymyxin and 4-HR. Combined therapy resulted in 80% survival rate compared to 40% for the polymyxin monotherapy. Interestingly, 4-HR doses of 30 mg/kg/day were in our experiments more effective than higher doses of 50 or 75 mg/kg/day. It is tempting to speculate that side-effects due to overdosing of 4-HR had a negative impact on the recovery of infected animals. Bacteriological analysis of parenchymatous organs of the animals euthanized 9 days after the end of combined treatment revealed absence of *K. pneumoniae* KPM9 cells in 75% of surviving animals, while all animals treated with the antibiotic alone were still carriers of the infection. Thus, the antibacterial preparation containing 4-HR suppressed formation of persister cells. We therefore propose that 4-HR might be an interesting alternative to sulfonamides and tetracyclines presently used as adjuvants for the treatment of klebsiellosis in humans.

The mechanism of action of 4-HR is polymodal and complex. Similar to other alkylresorcinols, the biological activity of 4-HR may be attributed to its action as a structural modifier of biopolymers and supramolecular structures such as membranes. [33, 34, 36, 49, 50] The amphiphilic nature of 4-HR seems to be responsible for its partitioning into and diffusion across cell membranes. Unlike cationic peptides, however, membrane integrity is not impaired by 4-HR. [51, 52] It has therefore been proposed that formation of complexes with macromolecules and membrane lipids results in increased microviscosity of the membrane lipids, which causes inhibition of their functional activity. [33, 36, 53] This membranotropic action of 4-HR explains the high efficiency of its combinations with the following antibiotics: polymyxin

(affecting membranes of gram negative bacteria), fluoroquinolones (inhibiting the activity of helicases located at the initial site of DNA replication), and amikacin, the effect of which depends on the transmembrane potential of bacterial cells. Besides its actions on membranes, 4-HR interacts with DNA [54] and proteins. The latter was demonstrated by studies using enzymes and immune system proteins as models. Effects were dose-dependent and linked to protein conformation and thus functional activity. [34, 50, 55, 56] Increased intracellular 4-HR concentrations induce a stress response leading to generation of reactive oxygen species (ROS) and RpoS (RNA polymerase, sigma factor S) activation. [57]

Due to their unspecific mode of action, 4-HR (and other alkylresorcinols) have unique properties in that they act on bacteria as well as on protozoans and helminths. [36] The outer membrane of gram negative bacteria seems to be the first target for 4-HR, which enables it to affect such forms of intracellular persistence as SCV-variants [58] and L-forms, [59] and to accumulate in phagocytes. [60] Model experiments *in vitro* revealed HR effect on biofilm formation and disintegration of mature biofilms. [61] It is tempting to speculate that the multimodal mode of action of alkylresorcinols prevents habituation or resistance. In fact, 4-HR-induced changes in microbial cells are similar to those observed under low-temperature stress (increased membrane viscosity and decreased enzymatic activity). Thus, adaptation of microbial cells both to low temperature and to elevated levels of alkylresorcinols is unlikely.

Conclusion

Alkylresorcinols are widespread in nature and are natural compounds present in large amounts in agricultural products (up to 1.5 g/kg in grain). Their daily consumption with food is 10–20 mg and is not considered harmful. [62] Alkylresorcinols are therefore considered to be bioactive nutrition components, [63] which are part of human metabolism without having negative consequences. [64] In experiments with mice, hexylresorcinol doses of up to 125 mg/kg were shown to have no carcinogenic properties. [65] Moreover, they exhibited antimutagenic [66] and antitumor properties. [67, 68] Consequently, 4-HR obtained regulatory authorization to be used for medical applications in human, [65] as well as in cosmetics and food industry. [69, 70] This status as safe compounds is an important advantage of alkylresorcinols, including 4-HR, and paves the way towards their clinical application as proposed antibiotic adjuvants. Our findings suggest that this strategy will allow for a more efficient use of established antibiotics and thereby reduce the risk of bacterial resistance.

Supporting information

S1 Table. Antibiotics used in the present study.

(PDF)

S2 Table. Interactions between 4-HR and various groups of antibiotics against clinical isolates of pathogenic gram negative bacteria.

(PDF)

S3 Table. Actual numbers of *K. pneumoniae* KPM9 cells in organs (cells/mL) from euthanized mice. Organs were analyzed 14 days after inoculation and treatment with the indicated doses of Polymixin B (PmB) and 4-HR for 5 days. For each organ, the range of bacterial counts in contaminated surviving animals (cells/mL) is indicated. Numbers in parenthesis: number of contaminated surviving animals / number of total surviving animals. Total number of animals was 10 per group. A ratio of 1/8 would thus describe a situation where 8 out of 10 mice did survive. From these 8 surviving animals, the respective organ of only one animal was still

contaminated.

6 DISCUSSION AND OUTLOOK

In the context of the presented PhD thesis, strategies to improve non-viral gene delivery have been investigated on three levels. These levels are from innermost to the outside: The lipid composition of the nanoparticle, the interactions of lipid-based nanoparticles with DNA, and the decoration of the lipid nanoparticle surface with shielding and targeting moieties. On top, strategies to improve the preclinical investigation of nanomedicines using the zebrafish embryo animal model have been proposed. Selected points of these four working packages shall be discussed and put into a larger context in the following sections.

6.1 LIPID-BASED GENE DELIVERY VEHICLES

The first attempts towards lipid-based gene delivery were made in the late 70's and involved phosphatidylcholine. [102] This report inspired a number of researchers to use different phosphatidylcholine-based formulations to deliver genetic materials to a wide variety of organisms. [103–106] However, phosphatidylcholine, a zwitterionic molecule, showed poor gene delivery efficiency compared to lipid compounds developed later. The next important discovery was made in the late 80's when Felgner et al. synthesized the first cationic lipid N-[1-(2,3-dioleyloxy)-propyl]-N,N,N-trimethylammonium chloride (DOTMA). [107] Compared to previous compounds, this cationic lipid was highly effective in gene delivery. As a consequence, cationic lipid-based gene delivery gained momentum and in the following years, a number of cationic lipids were synthesized and published. [108–110] It seemed as if cationic lipids were the way gene delivery is done. In fact, cationic lipids offer a number of advantages, including very high DNA condensation capacity, and thereby a good protection of the encapsulated nucleic acids, [111] and facilitated interactions between the pos-

itively charged nanoparticle and the negatively charged cell membranes. [112] Up to this day, cationic lipids represent the most commonly used gene delivery systems due to these advantages and the simplicity of nanoparticle/DNA complexation. [113, 114] However, cationic lipids also suffer from some severe drawbacks, including unspecific interactions with cell membranes, [115] accumulation in highly negatively charged tissues such as the lungs, [116, 117] and interactions with cellular proteins leading to cytotoxicity. [118–120] It is therefore very important to weigh between efficiency and toxicity of a cationic lipid-based gene delivery system.

A solution to this problem came in the early 2000's with the synthesis of novel ionizable lipids for gene delivery. [121, 122] Ionizable lipids do not carry a permanent cationic charge but are designed to be positively charged only where necessary (*e.g.*, during complex formation) and uncharged when a cationic charge is detrimental (*e.g.*, in the blood circulation). For the design ionizable lipids, the pKa value plays a very important role. For example, the most efficient ionizable lipidoids of the Anderson group and ionizable lipids of the Cullis group both show pKa values in the range of 6.0 - 6.8. [9, 123, 124] This way, ionizable lipid/nucleic acid nanoparticles can be formed at low pH (*e.g.*, pH 4) where the lipid is ionized and therefore carries a cationic charge to ensure proper DNA condensation. Upon injection into the blood stream (or after buffer change to pH 7.4), the complex is neutral and does therefore not interact with serum components or cell membranes, thereby ensuring a prolonged circulation half life. After (targeted) uptake into the cell, the lipid becomes charged again due to the acidification of the endosome. The ionized lipids can then interact with negatively charged lipids of the endosomal membrane, leading to a lipid flip-flop and subsequent displacement of the negatively charged nucleic acids, resulting in endosomal escape of the encapsulated cargo. [125, 126] Additionally, ionizable lipids often show reduced cytotoxicity due to their transient

charge as opposed to permanently charged cationic lipids. [127]

However, the syntheses of such sophisticated lipid compounds are complex, include several reaction steps and are therefore often associated with low yields. It was therefore the goal in **Chapter 1.2** to evaluate the feasibility of a one-pot approach based on double-reactive amination to obtain short-chain aminolipid compounds for gene delivery. The molecular structure of lipids for gene delivery can generally be divided into three categories: The headgroup, the tailgroup, and a linker functionality that connects head- and tailgroup. The linker functionality can have an important influence on the flexibility of charge presentation and biodegradability. [128] Owing to the nature of the reaction, however, the presented library consisted only of head- and tailgroups, whereas a linker functionality was not introduced. In this study, we could show that short-chain aminolipids are successfully synthesized using double-reactive amination and that methoxy-headgroups and C₁₂ tails are superior to other headgroups and C₁₀ tails. Because the study was focused on the feasibility of the reaction and the influence of a small number head- and tailgroups on transfection efficiency, no emphasis was paid on the pKa of the final products, which is considered an important factor nowadays. This flaw became obvious when combining our potentially ionizable aminolipids with cholesterol. The aim of replacing the permanently charged cationic lipid 1,2-dioleoyl-3-(trimethylammonium) propane (DOTAP) with aminolipids was not achieved. There was no particle formation, probably due to the absence of any charge that could condense DNA within the nanoparticle. Surprisingly, when DOTAP was combined with aminolipids instead of cholesterol, a number of candidates were able to improve the transfection efficiency compared to conventional DOTAP:cholesterol nanoparticles. A possible explanation for this phenomenon could be the small size of aminolipid headgroups and their short tailgroups. This facilitates lipid rearrangement within the membrane leaflets

of small multilamellar nanoparticles, which in turn reduces the nanoparticle membrane rigidity compared to cholesterol. It was shown for biological membranes that the reduction of the cholesterol content results in higher membrane fluidity, [129, 130] and therefore, increased likelihood of membrane rearrangements. Additionally, it was shown that cholesterol contents in membranes above 20 mol% decrease the the rate of membrane lipid translocation between membrane leaflets of a bilayer. [131] Therefore, the replacement of cholesterol with aminolipids could increase the rate of lipid rearrangement within the membrane which also facilitates lipid flip-flop between the bilayer of membranes. An additional explanation could be the ionization of aminolipids. It can be assumed that the nitrogen in aminolipids is ionized at lower pH, therefore increasing the net cationic charge of the nanoparticle. Anionic lipids of the endosomal membrane can then displace anionic DNA inside the nanoparticle and pair with the cationic lipids to form non-bilayer structures, [127] thereby disrupting the endosomal membrane and facilitating endosomal escape. The observed improvement of transfection efficiency could as well be the result of the combination of both effects. A further improvement of endosomal escape and therefore, improved transfection efficiency, could be achieved by introducing unsaturated lipid tails to aminolipids. Unsaturated lipid tails were shown to promote increased membrane fluidity, [132] thereby further increasing the likelihood of membrane rearrangements.

For DOTAP-based nanoparticles, aminolipids can be an interesting option to improve the transfection efficiency of said nanoparticles. However, some open questions remain. Cholesterol is a natural component of cell membranes whereas aminolipids are not. The toxic potential of aminolipids, and especially their long-term toxic potential, remains largely unclear. Therefore, the replacement of cholesterol with aminolipids is an effective but not necessarily safe option to improve the performance of DOTAP-based nanoparti-

cles. Moreover, the increase in transfection efficiency was only observed for DOTAP-based nanoparticles, but not for nanoparticles based on the ionizable lipid dilinoleylmethyl-4-dimethylaminobutyrate (DLin-MC3-DMA). This shows once more that there is no "one size fits it all approach" and that further research is necessary to improve our understanding of lipid components and their influence on interactions between nanoparticles and cells or even organisms. To improve our understanding of the underlying principles, further research with an expanded lipid library, including longer lipid tail lengths (*e.g.*, C₁₄, C₁₆, C₁₈) and unsaturated lipid tails, as well as a larger number of headgroups is needed. Regarding the headgroup, special emphasis should be put on the pKa value of the nitrogen group to obtain ionizable lipids that are able to form nanocomplexes together with DNA without the need for the cationic lipid DOTAP. Conclusively, the presented data demonstrates the validity of our approach to improve a clinically relevant nanoparticle formulation and deepens our understanding of the influence of molecular structures on lipid-based gene delivery.

6.2 DNA-NANOPARTICLE INTERACTION

Besides the lipid composition of nanoparticles, the type of DNA is another major contributor to gene delivery efficiency. Optimized DNA molecules such as minicircle DNA, which are devoid of the bacterial backbone that usually present in plasmid DNA, are associated with higher gene delivery efficiency and transgene expression levels, [133, 134] which was also observed in our study. (**Chapter 2.1**) [44] There are a number of explanations for the superior performance of minicircle DNA compared to its parental plasmid counterpart. These include for example the reduction of immunogenicity and epigenetic silencing due to removal of sequences of bacterial origin, [41, 42, 135] the increased mobility of smaller nucleic acid moieties in the cytoplasm and thereby improved nu-

clear translocation, [136–140] or higher numbers of minicircle DNA molecules delivered compared to its larger parental plasmid when the same mass of DNA is used. [141]

There are a number of papers in which the total amount of delivered DNA was quantified using quantitative polymerase chain reaction (qPCR) [142–145] or in which equimolar amounts of plasmids were delivered to remove the numerical bias on the superiority of minicircle DNA over parental plasmid DNA. [146–149] However, neither of these methods are able to provide information on the interactions between DNA molecules and nanoparticles and the latter approach is additionally biased by the fact that calculations might not properly reflect the actual experimental conditions. To improve the understanding of DNA-nanoparticle interactions, fluorescence cross-correlation spectroscopy (FCCS) was applied in **Chapter 2.1**. The investigation of lipoplexes of DNA and either a cationic lipid (DOTAP), an ionizable lipid (DLin-MC3-DMA), or a commercially available transfection reagent (Lipofectamine 3000) showed that DNA-nanoparticle interactions were different for each formulation. This observation can be explained by the structural differences of nanoparticles depending on the nanoparticle formulation. While DOTAP- and DLin-MC3-DMA-based formulations both adopt a small multilamellar vesicle structure where the nucleic acid is sandwiched between the lipid bilayers (Figure 1 and [36]), Lipofectamine 3000 is a liposomal formulation. According to the manufacturer, nucleic acids are mainly attached to the surface of the liposome but are not internalized. [150] However, the information on Lipofectamine 3000 is sparse due to its proprietary status. Therefore, it is difficult to draw further conclusions. Interestingly, our FCCS experiments correlate with these data since high DNA binding was observed for the multilamellar DOTAP- and DLin-MC3-DMA-based formulations and only weak binding was observed for Lipofectamine 3000-DNA interactions. Furthermore, the method allows to

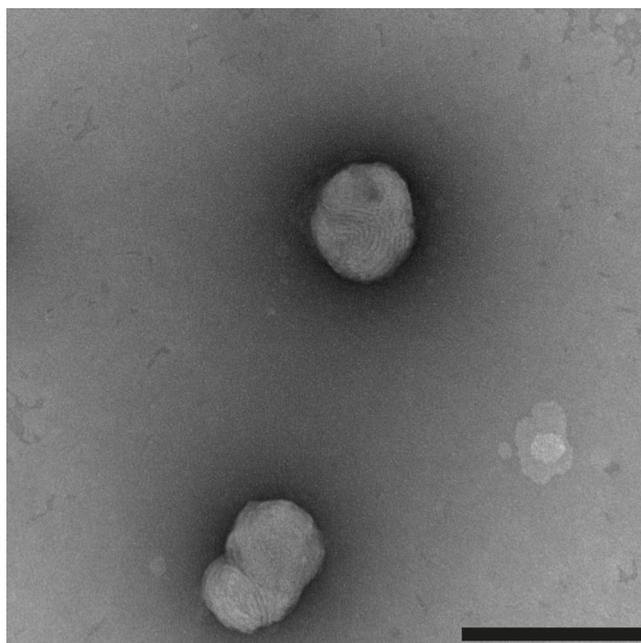

Figure 1: Transmission electron microscopy of DOTAP:cholesterol nanoparticles. The figure shows that DOTAP:cholesterol lipid nanoparticles (LNPs) adopt a small multilamellar vesicle structure. Nucleic acids are not only attached to the surface of the LNP but are mainly sandwiched between lipid bilayers by means of electrostatic interactions between the anionic phosphate backbone of DNA and cationic lipids. Scale bar = 200 nm.

determine the number of DNA molecules per nanoparticle after lipoplex formation. This number has so far only been calculated.

However, the method has some limitations as well. First, the method aims to determine interactions between nanoparticles and DNA. The method gives no information on where possible losses of DNA or nanoparticles occur but can only provide information on the final product after complexation (*i.e.*, lipoplexes). Second, the method provides only information on the interaction between DNA and nanoparticles but it cannot provide information on interactions between DNA and specific lipid components of the formulation. To improve our understanding of lipid-based gene delivery, it would be very interesting to determine which components of a formulation interact with DNA. For example, Kulkarni et al. applied cryo-TEM and molecular modeling to de-

termine interactions between formulation components and nucleic acids. [36] A method that could elucidate this question could improve formulation development, particularly when fine-tuning of a formulations towards specific needs is required. Conclusively, the measurements demonstrated that assumptions based on calculations are flawed and therefore, may lead to wrong conclusions. Furthermore, it is not possible to draw universally applicable conclusions that are valid for all lipid-based transfection reagents but the interactions have to be determined for each individual formulation.

FCCS is a very powerful technique with a wide variety of possible applications. An excellent in-depth discussion of FCCS and its possible applications is provided by Naredi-Rainer. [151] In addition to DNA-nanoparticle interactions after complex formation, FCCS can also be applied to elucidate the behavior of lipoplexes in contact with serum proteins, [152–154] or the extracellular matrix, [155,156] and to characterize drug-loaded nanocarriers in the blood circulation. [157] Further applications include the determination of nanoparticle uptake into cells, [158,159] and, importantly, the intracellular fate of lipoplexes and DNA molecules. [158,160–163] The latter is of special importance because additional information on the behavior of lipoplexes following uptake into cells is highly needed. The method can provide information about the extent and the duration of protection of nucleic acids by lipid-based nanoparticles after uptake into cells. It is known that nucleic acids need to be protected by the nanocarrier also within the endo-/lysosome and that the composition of the nanocarrier influences endosomal escape. [164] However, nucleic acids must dissociate from the lipid-based nanocarrier prior to nuclear translocation in order to successfully transfect a cell. It was shown that the nucleus is inaccessible to DNA complexed with cationic lipids (in contrast to DNA complexed with cationic polymers). [165,166] The lipoplex of DNA and nanocarrier is considered unable to cross the nuclear membrane due to the small size of the

nuclear pore of approximately 25 nm, [166,167] but even if it is injected directly into the nucleus, no gene expression is observed for cationic lipid/DNA complexes. [112,168] This is due to the fact that the nanocarrier not only protects the nucleic acid from nucleases but by the same mechanism makes it inaccessible to the transcription machinery of the cell as well. Therefore, the timepoint and the location of lipoplex dissociation are important characteristics to understand successful transfection. It was shown that the distance between the place of lipoplex dissociation and the nucleus of the cell is crucial [169] and that only 1% of DNA injected into the cytosol arrives in the nucleus, [165,168,170] likely due to degradation of DNA by cytosolic nucleases. [111] FCCS could monitor DNA and nanoparticles and allow to determine the spatial and temporal point at which they dissociate, thereby improving our understanding of intracellular processes crucial for successful transfection.

6.3 TARGETING AND BLOOD CIRCULATION PROPERTIES

One of the major advantages of nanoparticulate drug or gene delivery systems is the possibility to direct these nanomedicines to specific cell populations within the body using a targeting approach. The first conceptualization for targeted medicines was made over a century ago. It was in 1906 when Paul Ehrlich formulated the concept of a 'magic bullet' that would enable site-specific drug delivery while simultaneously eliminating off-target toxicity. [171] However, the translation from the concept to its actual application took a long time. It was in the field of oncology where the usefulness of nanoparticle-mediated targeted drug delivery first became apparent to the wider scientific community after the discovery of the Enhanced Permeation and Retention (EPR) effect by Matsumura and Maeda in 1986. [172] According to this publication, exploiting this effect would enable accumulation of nanoparticulate drug delivery systems in solid tumors. Despite the fact that the extent of this

effect is still debated until today (the effect is pronounced in mice models but not generally applicable to human tumors [173,174]), the field of nanomedicine gained popularity and experienced a rapid growth following this discovery and up to this day, the majority of nanoparticulate drug delivery systems still rely (or claim to rely) on the EPR effect. [174,175]

Targeting approaches can be categorized into two distinct categories: passive targeting and active targeting. Passive targeting does not require targeting ligands but relies on the properties of the nanoparticulate delivery system or the targeted tissue. Consequently, passive targeting approaches show reduced batch-to-batch variability and facilitated synthesis, formulation and characterization. [176] Properties enabling passive targeting include for example the size and the surface charge of nanoparticulate delivery systems or inherent properties of the target tissue (or tumor) such as the EPR effect. The size of a nanoparticulate delivery system influences its biodistribution and thereby enables passive targeting. For example, nanoparticles exceeding 200-250 nm are predominantly cleared by spleen and liver-resident macrophages of the reticuloendothelial system (RES), leading to accumulation in these organs. [177–181] Interestingly, the extent of serum opsonization after injection in the blood circulation is influenced by the size as well. It was shown that nanoparticles with a diameter below 100 nm are less susceptible to opsonization by serum proteins, thereby prolonging the blood circulation half-life *in vivo*. [182, 183] The surface charge of a nanoparticle can influence its biodistribution as well with highly positively charged nanoparticles accumulating predominantly in the lungs and highly negatively charged nanoparticles being cleared by cells expressing scavenger receptors such as liver endothelial cells. [184,185] Finally, the exploitation of the EPR effect is possible due to two characteristics of solid tumors: First, tumor growth requires accelerated formation of blood vessels (neovascularization) to provide the tumor with nutrients and oxygen. Be-

cause normal vascularization requires a fine balance of pro- and antiangiogenic factors which is shifted towards proangiogenic factors in tumors, novel blood vessels supplying the tumor are often leaky. [186,187] This enables nanoparticle extravasation from the blood vessel and accumulation in the tumor tissue. Second, the tumor growth impairs lymphatic drainage that would normally lead to nanoparticle clearance from the tumor, thereby pronouncing nanoparticle accumulation in the tumor tissue. [188,189] However, discussions on this topic are ongoing and in many tumors in humans, including pancreatic cancer, the EPR effect is not observed. [189]

In contrast, active targeting relies on one or more targeting ligands. On the one hand, this increases variability and complexity of the system. On the other hand, active targeting allows for much more specific direction of nanoparticles to desired cell populations. [190] There is a wide variety of targeting ligands from small molecules, over peptides, to antibodies, and antibody fragments. [50–62] Interestingly, an advantage of antibody fragments is the lack of the Fc domain, resulting in reduced uptake by phagocytic cells of the RES, thereby increasing blood circulation time. [191–193] Active targeting relies on cellular surface structures (*e.g.*, receptors) that are overexpressed or exclusively expressed in the targeted cell population. [194,195] The targeting ligand is then responsible for the specific uptake into the targeted cell population through interaction with the targeted receptor. Moreover, in the case of internalizing receptors, improved uptake into cells through specific pathways is another advantage of targeting approaches. [196]

With respect to liver targeting, a large majority of targeting approaches rely on either the asialoglycoprotein receptor (ASGPR) or the low density lipoprotein receptor (LDLR). [66, 197, 198] However, both of these approaches suffer from drawbacks. Targeting to the ASGPR requires complex syntheses to obtain the multivalent glycans that interact with the ASGPR [199] and

for LDLR targeting, it was shown that a majority of nanoparticles are recycled back to the cell exterior after uptake, thereby reducing the delivery efficiency. [200] Consequently, novel targeting approaches are needed. The proposed strategy presented in **Chapter 3.1** relies on peptide sequences of viral origin, namely sequences of the large envelope protein of hepatitis B virus (HBVpreS). It was shown that this peptide sequence interact with the sodium-taurocholate cotransporting polypeptide (NTCP). The HBV specifically targets and infects hepatocytes in a highly efficient manner. [63] Optimization of the targeting peptide showed improved systemic circulation behavior of shorter myristoylated peptide sequences (Myr-preS2-31) as opposed to longer peptide sequences (Myr-preS2-48). This can be attributed to the increased immunogenicity of longer peptides [201–204] resulting in a reduced circulation half life. Furthermore, the ligand density plays an important role in efficient delivery. Too low ligand densities (*i.e.*, ≤ 0.125 mol%) do not promote sufficient uptake into hepatocytes, probably due to a decreased number of interactions between targeting ligand and NTCP. Too high ligand densities (*i.e.*, ≥ 0.5 mol%) showed increased clearance from the blood circulation, probably due to immune responses. A ligand density of 0.25 mol% (corresponding to around 80 maleimide-conjugated Myr-preS2-31 moieties per nanoparticle) showed an optimal balance between targeting efficiency and circulation properties. Interestingly, the high species-dependency of HBV (which is unable to infect murine hepatocytes [205]) was not observed for this targeting peptide. Indeed, Myr-preS2-31-modified liposomes showed a pronounced uptake into murine hepatocytes. Finally, the presented lipopeptide can be synthesized by standard solid phase peptide synthesis in high yields and purity. This eliminates complex syntheses like in the case of ASGPR targeting. [65, 206, 207] Taken together, these results demonstrate the viability of the approach to exploit targeting mechanisms found in pathogens for successful drug or gene therapy.

Moreover, this viral peptide allows specific targeting of hepatocytes whereas other pathogens such as *Plasmodium spp.* initially target Kupffer cells before they are able to infect hepatocytes. [208]

Efficient targeting is only one aspect of successful drug or gene delivery using nanoparticles. Another important aspect comprises the blood circulation properties. Prolonged systemic circulation half-life is a prerequisite for successful targeted delivery of nanomedicines because it extends the timeframe during which nanomedicines can interact with the targeted surface structures. Even the most sophisticated and efficient targeting approaches are likely to result in clinical failure if the nanocarriers are rapidly cleared from circulation following intravenous injection. Unshielded nanoparticles are characterized by low systemic circulation half-life *in vivo* [209, 210] due to opsonization of the nanoparticle surface with opsonin proteins (complement compounds, immunoglobulins, fibronectin, and apolipoproteins [211]) and subsequent recognition by and uptake into phagocytic cells of the RES. [212] Hydrophobic surfaces are particularly prone to opsonization due to hydrophobic interactions with opsonins. A possible solution to this problem consists of surface modification with hydrophilic substances. [213] The first reports on the use of polyethylene glycol (PEG), a hydrophilic polymer, were published in 1977. In their study, Abuchowski et al. demonstrated prolonged systemic circulation half-life of bovine serum albumin and liver catalase following PEG modification (PEGylation). [214] The successful demonstration of prolonged blood circulation properties of PEGylated proteins inspired several researchers to investigate the applicability of the PEGylation concept to improve the circulation behavior of nanoparticles in the 80's and 90's. [72, 215, 216] The first PEGylated protein product, Adagen®[®], an adenosine deaminase enzyme for the treatment of severe-combined immunodeficiency (SCID) was approved by the FDA in 1990 [217] and the first PEGylated nanoparticle product, Doxil®[®],

in 1995. [47] Since that time, enhancement of circulation properties using PEGylation has been established as the most widely applied strategy to increase the blood circulation time of nanomedicines. [210, 218]

Advantages of PEGylation include not only reduced opsonization, but also reduced tendency of nanoparticles to aggregate due to the steric hindrance provided by PEG [219, 220] and, to a certain extent, shielding of excessive surface charge due to an increased distance between nanoparticle core surface and nanoparticle PEG brush surface, resulting in so-called 'stealth' nanoparticles. [221] Despite these advantages, an increasing number of researchers raise concerns towards PEGylation strategies due to the emergence of Anti-PEG antibodies. [222–225] There is increasing evidence that the phenomenon of accelerated blood clearance (ABC), *i.e.*, the gradual reduction in efficacy of PEGylated nanoparticles following repeated administration, is closely connected to the emergence of Anti-PEG antibodies. [226, 227] The reduced efficacy of PEGylated nanomedicines due to immune reactions to PEG is even more concerning considering the fact that Anti-PEG antibodies were even found in healthy individuals who were not treated with PEGylated nanomedicines so far. The emergence of Anti-PEG antibodies in healthy individuals is likely attributable to exposure to PEG moieties in products of everyday life such as cosmetics. [228, 229] Furthermore, there is indication that the anchoring phospholipid causes specific and nonspecific immune reactions as well, [82] likely due to the negative charge at the phosphate group of DSPE-PEG variants. [230, 231]

Taken together, these findings demonstrate the need to search for alternatives to PEG. Alternatives to PEG which exhibit similar properties with respect to water solubility or immunogenicity include, for example, hyperbranched polyglycerol (hbPG) [232–237] and polysarcosine (pSar) moieties. [238, 239] The applicability of the latter to enhance blood circulation properties of lipo-

somes was investigated in **Chapter 3.2**, whereas the former motivated us to establish a zebrafish *Salmonella* infection model (**Chapter 4.1**) as discussed later. We could show that bisalkyl polysarcosine (BA-pSar) is a valuable alternative to PEG. BA-pSar (more precisely: BA-pSar₁₀₂) was successfully and reproducibly synthesized with high yields ($\geq 90\%$) in a controllable one-step reaction. As discussed for lipid synthesis in the section 6.1 LIPID-BASED GENE DELIVERY VEHICLES, polymer synthesis often involves multi-step reactions as well, leading to high variations between different batches. Batch-to-batch variability is a serious problem in polymer chemistry for nanoparticles, especially when it comes to scale-up. [240,241] The obtained BA-pSar was successfully incorporated into liposomes based on the Doxil® formulation, yielding nanoparticles comparable to their DSPE-mPEG2k-modified counterparts with respect to size and polydispersity index (PDI) and with similar charge shielding properties. BA-pSar was firmly anchored in the lipid bilayer via its bisalkyl tails, thereby omitting the charged DSPE moiety, one of the structural properties responsible for complement activation. Further end group modification (*i.e.*, acetylation, BA-pSar₁₀₂Ac) removed the positive charge of the terminal amine group present in unmodified BA-pSar. As a consequence of this modification, uncharged BA-pSar₁₀₂Ac showed reduced immunogenicity in the complement activation assay with the immunogenicity increasing in the following order: BA-pSar₁₀₂Ac < DSPE-mPEG2k < BA-pSar₁₀₂. Notably, pSar is the polymer of sarcosine, an intermediate in glycine metabolism which is classified to be of low concern by the United States Environmental Protection Agency (EPA). [246] Therefore, immune responses to sarcosine are unlikely to occur. However, the ethylene glycol monomer is considered non-immunogenic as well, [224] showing that polymeric materials do not necessarily share the immunogenic properties of their respective monomer. This in combination with the large gap between first applications of PEGylated nanomedicines and the

discovery of immune reactions against PEG shows that long-term trials would be needed to rule out possible immune reactions to pSar-modified nanoparticles. Interestingly, the terminal amine end group of unmodified BA-pSar allows its modification with different moieties as well, thereby enabling straightforward coupling of *e.g.*, targeting moieties directly to BA-pSar. For example, the terminal amine of BA-pSar could be modified with maleimide [242] enabling coupling of thiolated moieties as described for Myr-preS2-31. [66] This way, the liver targeting approach described before could also be applied to BA-pSar-modified liposomes. Alternatively, BA-pSar could be synthesized with shorter alkyl chains and incorporated into ionizable lipid formulations based on DLin-MC3-DMA or DLin-KC2-DMA. Similar to short chain PEG anchors, the short chain alkyl anchor would allow rapid dissociation of BA-pSar shielding from the lipid nanoparticle, leading to interactions with apolipoprotein E (ApoE), thereby enabling targeted uptake into hepatocytes. [9, 127, 243] Finally, in the highly predictive zebrafish animal model, BA-pSar-modified liposomes circulated freely similar to DSPE-mPEG2k-modified liposomes whereas unmodified liposomes were cleared from circulation after 24h. [244, 245] Conclusively, the presented results demonstrate that BA-pSar moieties can be a valuable alternative to PEG when it comes to the improvement of systemic circulation properties of and the reduction of immune reactions to lipid-based nanomedicines.

6.4 ZEBRAFISH EMBRYO *Salmonella* INFECTION MODEL

There are other possibilities to improve the circulation behavior of liposomes in a similar manner to PEG. One proposed class of substance is hyperbranched polyglycerol (hbPG). [232–237] In cooperation with the group of Prof. Mark Helm at the University of Mainz, we were asked to evaluate the blood circulation behavior of hbPG-modified liposomes in our zebrafish embryo animal

model (Figure 2). To our surprise, the hbPG-modified liposomes exhibited a

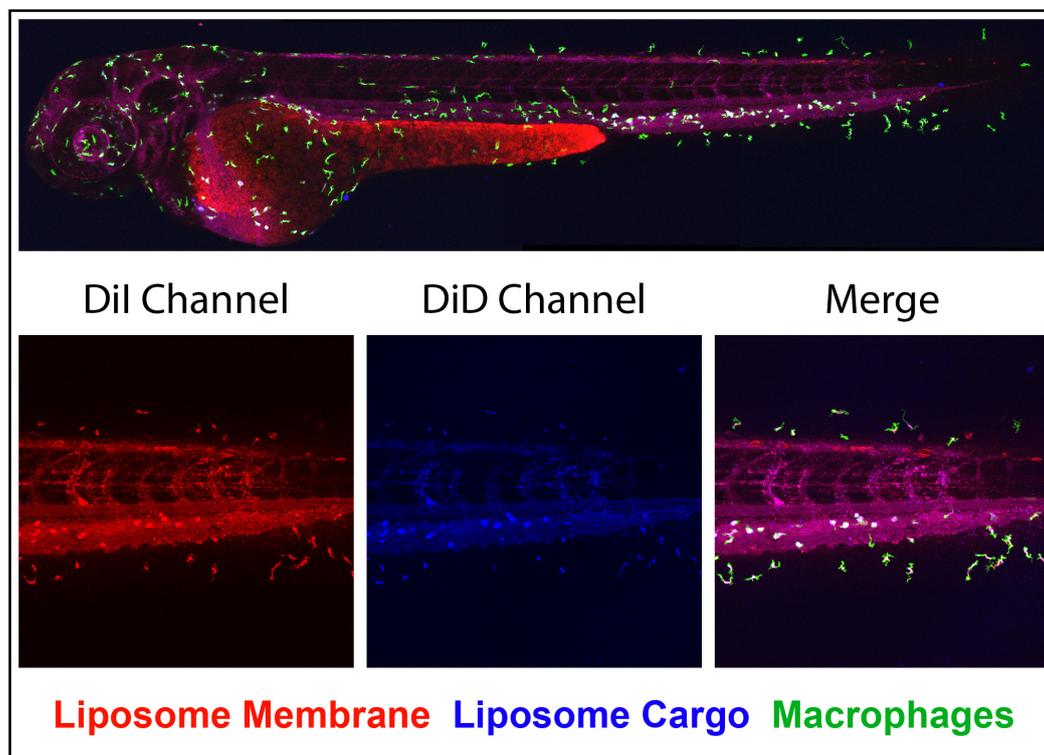

Figure 2: Macrophage accumulation of hbPG-modified liposomes. The figure shows the accumulation of hbPG-modified liposomes in macrophages four hours after injection. The labeled liposomes (red) encapsulating DiD (blue) as a liposome cargo model clearly accumulate in macrophages (green) of Tg(mpeg:Gal4;UAS:Kaede) zebrafish visualized by fluorescence colocalization of red, green, and blue dye, resulting in white color within the macrophages.

rapid uptake not only into macrophages with access to the blood circulation (round shape) but also into tissue-resident (star shape) macrophages. Except for the predominant uptake into macrophages, image analysis revealed a favorable blood circulation behavior, indicated by the diffuse staining pattern of the liposome membrane dye. [85] Therefore, hbPG-modification of liposomes represents a means to target macrophages. These unexpected results motivated us to investigate the applicability of hbPG-modified, antibiotics-loaded liposomes to treat systemic infections of pathogenic microorganisms that per-

sist within macrophages. *Salmonella spp.*, along with other pathogenic microorganisms such as *Mycobacterium tuberculosis* possess the ability to persist and even replicate within macrophages within so-called Salmonella containing vacuoles (SCV). [93–96, 247] This behavior is very problematic because these pathogenic microorganisms can evade an antibiotic treatment by this strategy, especially if the used antibiotics show poor cell membrane penetration properties (such as tobramycin). [248] After termination of the antibiotic treatment, these microorganisms can reemerge due to uncontrolled replication within the macrophage leading to a burst of the macrophage and release of the microorganisms. This behavior was observed time and again during our experiments. Consequently, novel treatment approaches are needed to tackle macrophage-persistent pathogenic microorganisms. Another serious problem in the field of antibiotic treatment is the emergence of antibiotic resistance. In fact, the increasing inefficiency of antibiotic compounds for the treatment of infectious diseases caused by pathogenic microorganism is potentially one of the most serious problems of our century. [86] Widespread antibiotic resistance could well render present treatment regimens inefficient, leading to a relapse into a situation similar to the pre-antibiotic era during which infectious diseases caused by pathogenic microorganisms were one of the major causes of death. [249–251] However, at the same time the development of novel antibiotic compounds is unattractive to the pharmaceutical industry due to concerns that return of investment cannot be achieved because of strict regulations and due to the high costs associated with the development of novel antibiotic compounds. [252] One of the drivers of high costs are expensive animal trials. We therefore proposed the relatively inexpensive zebrafish animal model as a pre-selection tool for screenings. Not only does the high reproduction rate of zebrafish allow for high-throughput screenings but the pharmacokinetics of fluorescent liposomal antibiotic formulations can be assessed as well due to the transparency of this

animal model.

In view of this, we developed a zebrafish embryo *Salmonella* infection model (**Chapter 4.1**) to assess the applicability of hbPG-modified liposomes encapsulating antibiotics and of 4-hexylresorcinol as an antibiotic adjuvant (**Chapter 4.2**). To establish the *Salmonella* infection model, the dose of bacteria, the site of injection, and the temperature at which zebrafish embryos were kept, were assessed. Optimal results were obtained with a bacteria dose of 300 CFU injected into the Duct of Cuvier (termed vasculature injection) and when zebrafish were kept at 35°C. This temperature was chosen because it is the best compromise between human body temperature (37°C) and ideal zebrafish culture temperature (28°C). Unfortunately, zebrafish embryos did not survive at 37°C. The model was then validated using two antibiotics with different membrane penetration properties: Ceftriaxone (membrane penetrating) and tobramycin (no membrane penetrating). Survival analysis clearly showed the difference between the two antibiotics. Ceftriaxone-treated zebrafish exhibited high survival rates (almost 100%) and tobramycin-treated zebrafish showed reduced survival rates of only 50%. The results of the survival analysis were confirmed by qualitative fluorescence-based confocal imaging: Macrophages were almost completely free of *Salmonella* in ceftriaxone-treated zebrafish embryos whereas in tobramycin-treated zebrafish the majority of macrophages was still infected with large amounts of bacteria. Both treatments showed rapid clearance of bacteria in circulation. Therefore, we attributed the observed effects to the different penetration properties of the antibiotics.

However, despite the successful establishment of an animal model we were unable to demonstrate the superiority of either hbPG-modified liposomal formulation. There are several reasons for this failure: First, compared to free ceftriaxone, liposomal ceftriaxone did not improve bacteria eradication within macrophages and therefore, survival of the zebrafish (Figure 3). This is at-

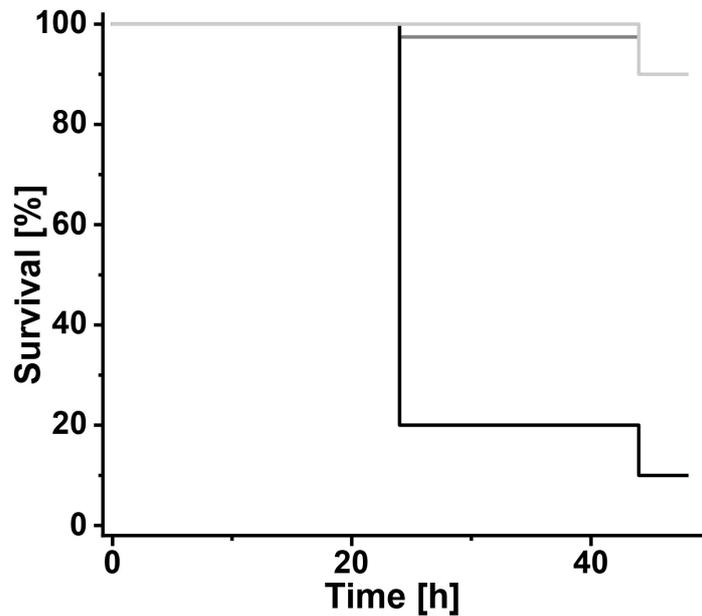

Figure 3: Survival analysis of zebrafish embryos infected with *Salmonella* treated with free or liposomal ceftriaxone. The figure shows the survival analysis of zebrafish embryos infected with 300 CFU *Salmonella*. Zebrafish were either treated ceftriaxone-loaded hbPG-modified liposomes (light grey), free ceftriaxone (dark grey) or PBS (black). There is no significant difference between liposomal and free ceftriaxone. (n=20).

tributed to the ability of free ceftriaxone to penetrate membranes. Therefore, macrophage-targeting liposomes are not necessary to eliminate bacteria within macrophages. Second, tobramycin encapsulated within macrophage-targeting liposomes was unable to eradicate bacteria in circulation following its intracellular release from the liposomes within the macrophages. Consequently, the bacteria in circulation were able to replicate and led to rapid death of treated zebrafish. Generally, bacteria replication in the vasculature had a much more pronounced influence on the survival of zebrafish embryos compared to replication within the macrophages. Therefore, eradication of bacteria in circulation is necessary to determine the treatment efficiency of liposomal tobramycin. Third, if zebrafish were treated with a combination of free and liposomal tobramycin, the bacteria in the vasculature were successfully eradicated after

four hours. However, accumulation of hbPG-modified liposomes was not effective enough to eradicate bacteria in all macrophages within a short timeframe. Tobramycin shows a short circulation half-life of only 2-3 h and is predominantly eliminated renally in humans (93% within 24 h). [253] The half-life of tobramycin in zebrafish embryos is likely similar to that in humans due to the close analogy between zebrafish and mammalian kidneys. [254] Very few untreated macrophages are therefore sufficient to allow *Salmonella* survival and replication, leading to rapid reinfection. The high bacteria load in circulation in combination with the presence of bursted macrophages after 24 hours indicate such an effect. Fourth, polymer chemistry is, as already mentioned in the section 6.3 TARGETING AND BLOOD CIRCULATION PROPERTIES, associated with high batch-to-batch variabilities. Indeed, accumulation of hbPG-modified liposomes and circulation behavior varied to a large extent among the different experiments. These observations were made independent of the lipid composition of the formulation (Figure 4). Therefore, it is reasonable to assume that these differences are caused by the polymer. On top of that, our collaboration partner in Mainz had to change the supplier of educts for hbPG synthesis, thereby further increasing the variability of the synthesized polymers. Consequently, our fine-tuned animal model that allowed differentiation of free antibiotics struggled with the high variations inherent to the hbPG-modified liposomes (RSD up to 140% for survival after 24 h).

Possible solutions to these problems could be the decoration of liposomes with PEG350 and the use of a different strain of bacteria. First, decoration with short-chain PEG moieties such as PEG350 was shown to promote macrophage accumulation as well, as demonstrated by Sieber and co-workers. [245] An advantage of PEG350 is that it is commercially available as a well characterized, high quality product, thereby eliminating issues associated with high variability of small-scale polymer synthesis. Another possibility is the infection

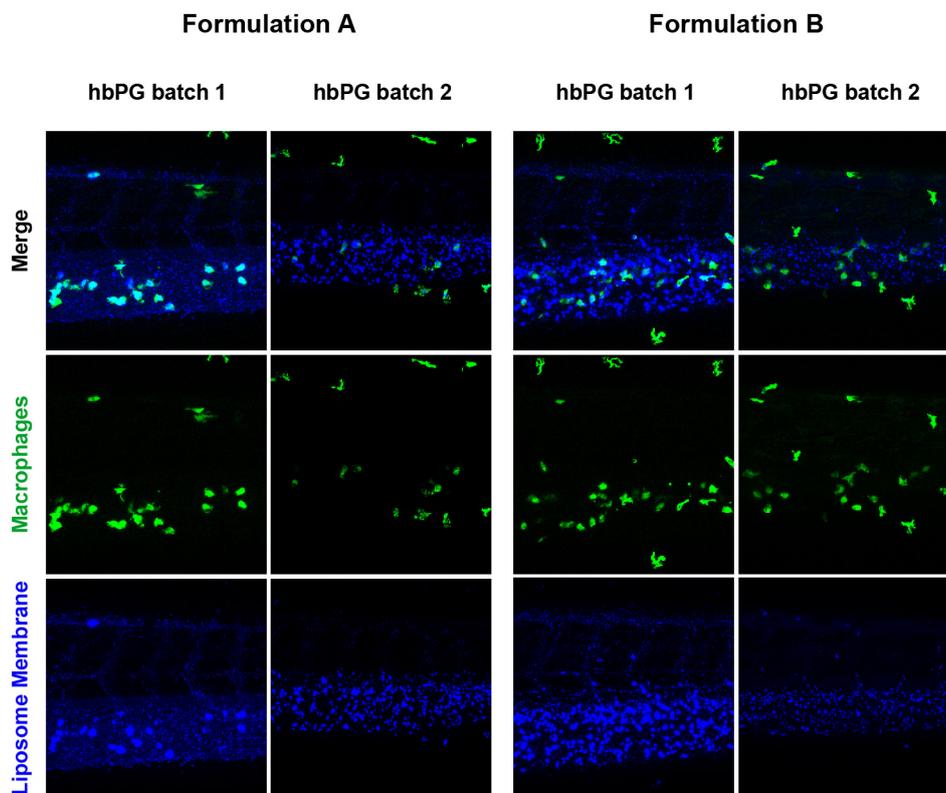

Figure 4: Confocal images showing the variability in macrophage accumulation and circulation behavior between two batches of hyperbranched polyglycerol (hbPG). The different hbPG batches lead to different macrophage accumulation and circulation behavior. Liposomes modified with hbPG batch 1 colocalized well with macrophages whereas liposomes modified with hbPG batch 2 showed only poor colocalization.

of zebrafish embryos with a different bacteria strain, namely the $TIMER^{bac}$ strain, a strain of *Salmonella enterica* serovar Typhimurium SL1344 published by Claudi et al. in 2014. [255] This bacteria strain expresses two different fluorescent proteins depending on the growth rate. Briefly, the bacteria express green fluorescent proteins in their replication phase and orange fluorescent proteins in the non-replicative status. Thus, $TIMER^{bac}$ can be used as a growth reporter. Using this strain, the effect of liposomal formulations of antibiotics on the intracellular replication of bacteria can be assessed qualitatively. This strategy does not allow for quantification of the effect but it could qualita-

tively demonstrate the applicability of the approach to eradicate intracellular pathogens *in vivo*.

In addition to the assessment of liposomal formulations of antibiotics, we employed our zebrafish embryo *Salmonella* infection model to assess the use of 4-hexylresorcinol (4-HR) as an antibiotic adjuvant, as well. Alkylresorcinols, including 4-HR, can be found in agricultural products such as grain and are considered safe bioactive nutrition components. [256] Doses up to 125 mg/kg showed no carcinogenic properties in mice [257] but possess antimutagenic [258] and antitumor properties. [259, 260] Alkylresorcinols are widely used in cosmetics and food industry [261, 262] and are authorized to be used in medical applications in humans. [257] 4-HR potentiated the activity of a selection of widely used antibiotics *in vitro* and *in vivo* as demonstrated in **Chapter 4.2**. Moreover, inclusion of 4-HR in antibiotic treatment was also highly efficient in eradicating persister cells and in preventing germination of spore forms. Both of these forms do not possess acquired antibiotic resistance but are considered an important link in the chain of antibiotic resistance development. The zebrafish *Salmonella* infection model was used to assess the benefit of combination therapy. The zebrafish was chosen as a model organism because it allows to monitor the survival of a large number of animals, thereby increasing the reliability of the data and decreasing the impact of outliers. 4-HR is poorly water soluble with a solubility of only 800 mg/L (determined experimentally by Nikolaev and co-workers). Therefore, preliminary experiments aimed to assess the tolerability of dimethyl sulfoxide (DMSO) injections into zebrafish embryos. Injections of 100% DMSO were not well-tolerated by zebrafish embryos (survival 60%; denaturation of the tissue surrounding the injection site) but the survival drastically improved when the DMSO concentration was lowered. Injections of 50% DMSO in Dulbecco's phosphate-buffered saline (DPBS) were better tolerated in zebrafish embryos with a survival of 100% of the treated fish

after 24 h. However, the transparent surrounding tissue shifted to a black/grey color upon injection, possibly due to interactions of DMSO with serum proteins and cellular proteins (denaturation). Consequently, DMSO concentrations had to be reduced further. Color shifts were not observed anymore for a concentration of 25% DMSO in DPBS (survival 100%), a concentration which allowed to dissolve 2 mg/mL 4-HR. Therefore, injections of the maximum volume possible in zebrafish embryos (5 nL) enabled treatment with concentrations of up to 100 mg/L 4-HR within the zebrafish. Concentrations of 4-HR up to 60 mg/L were tolerated by zebrafish (survival 100% after 28 h). However, the combination of *Salmonella* injection, antibiotics injection (polymyxin), and 4-HR injection led to a drop in survival below 25% after 24 h. We speculated that this drop is caused by the injuries inflicted to zebrafish embryos by three injections. Therefore, 4-HR and antibiotics were combined in one sample in further experiments to reduce the number of injections. However, zebrafish embryos did not tolerate these conditions as well. Even a reduction of 4-HR concentration in the zebrafish embryos to 10 and 20 mg/L did not improve the survival (25% after 24 h). Although 4-HR is toxic especially to water organisms, the initial experiments indicating tolerability up to a concentration of 60 mg/L seemed promising at first. However, the combination of all interventions likely led to a synergistic reduction in survival that was not observed for the single factors alone. Finally, we aimed to improve the survival by eliminating 4-HR from the injection schedule. Zebrafish embryos were injected only with *Salmonella* and polymyxin and the fish were maintained in zebrafish culture medium supplemented with 10 or 20 mg/L 4-HR. However, zebrafish embryos did not tolerate the presence of 4-HR in the culture medium at all: All fish died within 4 hours irrespective of the 4-HR concentration (Figure 5). Probably, zebrafish embryos do not tolerate 4-HR in doses as high as 10 mg/L over prolonged periods of time. It is reasonable to assume that the difference in tol-

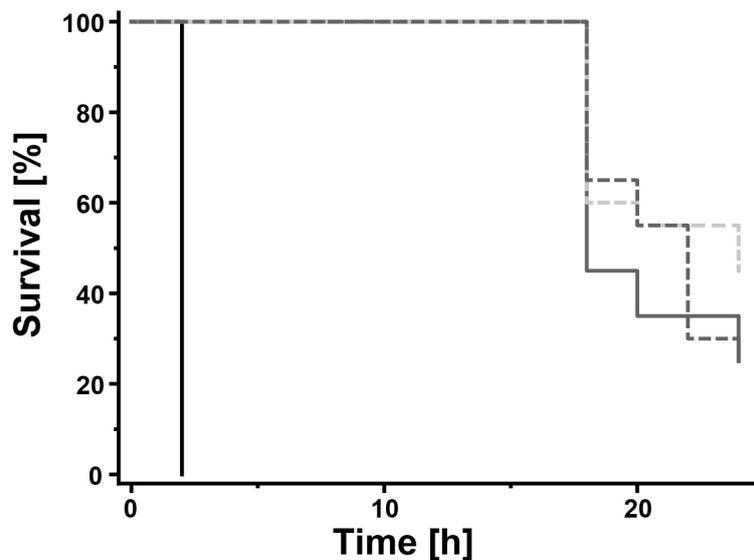

Figure 5: Survival analysis of zebrafish embryos treated with 4-hexylresorcinol (4-HR), Polymyxin, or combinations thereof. *Salmonella* infected zebrafish were treated with 100 pg Polymyxin (light grey dashed line), 20 mg/L 4-HR alone (dark grey solid line), 100 pg Polymyxin + 20 mg/L 4-HR (dark grey dashed line), or 100 pg Polymyxin in the presence of 20 mg/L 4-HR in the zebrafish culture medium (black solid line). Injected doses are given as the final concentration of 4-HR in the zebrafish embryos. (n=20).

erability between the two treatment variants (*i.e.*, 4-HR injection and addition of 4-HR to the medium) is caused by the different resulting plasma concentrations. The concept of absorption, distribution, metabolism, and excretion (ADME) can explain the observed effects. After injections of 2 ng 4-HR into zebrafish (total volume at the day of injection of up to 100 nL [263], resulting in a concentration of 20 mg/L in the fish), 4-HR is subjected to rapid elimination. The clearance of 4-HR in zebrafish can occur by several ways: Biliary elimination via the gall bladder and subsequent excretion via the intestine, renal excretion via the urine, elimination via the skin, and possibly elimination via the gills. Furthermore, a contribution of metabolism cannot be excluded. We therefore assume that intravenous injection of 4-HR results in transient exposure only. Compared to the volume of zebrafish culture medium (25 mL),

the total dose of 4-HR injected into all zebrafish embryos present in said volume of culture medium is negligible (40 ng). Injection of 4-HR is therefore in contrast to experiments in which the culture medium is supplemented with 4-HR. In this case, topical absorption of 4-HR from the culture medium overcomes excretion, resulting in a rapid increase of 4-HR plasma concentrations in the zebrafish. Additionally, accumulation of 4-HR in lipophilic environments cannot be excluded ($\log P = 3.45$ [264]). As a consequence, zebrafish embryos are exposed to 4-HR over a prolonged period of time and die rapidly due to toxic effects. A drawback of the zebrafish embryo model is the fact that we could not determine the contributions of metabolism and elimination to the clearance of 4-HR. Therefore, clearance mechanisms for 4-HR need to be elucidated in different animal models (*e.g.*, mice or rats) because the measurement of plasma concentrations in zebrafish embryos is very challenging. In fact, novel methods sensitive enough to perform pharmacokinetic measurements in zebrafish embryos have been published only very recently. [265,266] The technological advance may therefore enable pharmacokinetic studies in zebrafish in the near future.

Conclusively, our zebrafish embryo *Salmonella* infection model is probably the wrong animal model to investigate the effect of 4-HR (or other alkylresorcinols that share the specific toxicity towards water organisms) on the treatment of pathogenic microorganisms with antibiotics. Furthermore, the high variabilities in polymer chemistry resulted in highly variable circulation behavior and macrophage clearance for hbPG-modified liposomes. Therefore, the shortcomings in the preparation process of modified liposomes made it difficult to demonstrate the applicability of liposomal antibiotics formulations for the treatment of intracellular pathogens. Despite these setbacks, the established zebrafish embryo *Salmonella* infection model could be an interesting research tool for the screening of novel antibiotics because it was able to clearly differen-

tiate the two antibiotics. The differences in effectiveness of the two antibiotic compounds were reflected by both, survival analysis and confocal imaging and are in good accordance with the physicochemical properties of the antibiotic compounds. Moreover, the model can provide deeper insights into mechanisms of antibiotic therapy, especially if the established model were combined with the bacterial growth reporter *Salmonella* strain TIMER^{bac}.

7 CONCLUSION

In the context of this PhD thesis, four major working packages (**CHAPTERS 1-4**) were investigated. The presented working packages cover four areas of lipid-based gene and drug delivery from the inside to the outside, starting with nanoparticle lipid composition and ending with the application of the zebrafish embryo animal model.

First, an overview of the current state of lipid-based gene delivery was provided and factors influencing gene delivery *in vitro* and *in vivo* were discussed. Furthermore, the successful application of a simplified lipid synthesis for DNA delivery was demonstrated. Short-chain aminolipids synthesized in a straightforward one-pot synthesis improved the gene delivery efficiency of a clinically relevant lipoplex formulation. Moreover, molecular structures important for gene delivery were discussed theoretically and evaluated practically in a Structure-Activity-Relationship experiment (**CHAPTER 1**).

Second, a fluorescence-based tool to investigate DNA-nanoparticle interactions was evaluated. The investigation of fluorescently-labeled DNA and nanoparticles using FCCS enabled the determination of the number of DNA molecules per nanoparticle. Moreover, the tool revealed qualitatively different interactions with DNA depending on the type of lipid-based gene delivery vehicles. These results demonstrate that ideally, DNA-nanoparticle interactions should be evaluated for each individual formulation (**CHAPTER 2**).

Third, novel approaches towards targeted delivery and enhancement of circulation properties of nanomedicines were evaluated. The presented targeting strategy relying on peptides derived from hepatitis B virus promoted highly efficient and selective uptake into hepatocytes. Enhancement of circulation properties similar to PEG but with reduced immunogenicity was achieved using a shielding strategy based on bisalkyl polysarcosines (**CHAPTER 3**).

Fourth, a zebrafish embryo animal model for the screening of antibiotic compounds was established and validated. The model was used to evaluate liposome-based antibiotic therapy and antibiotic adjuvants. Shortcomings of polymer synthesis for liposome-based antibiotic therapy and high toxicity of the adjuvant to zebrafish embryos prevented further examinations. Despite these drawbacks, the basic model could be very useful for the screening of novel antibiotic compounds and, when combined with bacterial growth reporters, for mechanistic investigations of antibiotic treatments as well (**CHAPTER 4**).

Conclusively, the the findings of this PhD thesis aim to improve our understanding of lipid nanoparticle-based gene and drug delivery and to provide additional tools for their preclinical investigation.

Abbreviations

4-HR	4-hexylresorcinol
ABC	Accelerated blood clearance
ABR	Antibiotic resistance
ADME	Absorption, distribution, metabolism, and elimination
ASGPR	Asialoglycoprotein receptor
BA-pSar	Bisalkyl polysarcosine
Cas9	CRISPR-associated protein 9
CRISPR	Clustered regularly interspaced short palindromic repeats
DLin-MC3-DMA	Dilinoleylmethyl-4-dimethylaminobutyrate
DMSO	Dimethyl sulfoxide
DOTAP	1,2-dioleoyl-3-(trimethylammonium) propane
DOTMA	N-[1-(2,3-dioleoyloxy)-propyl]-N,N,N-trimethylammonium chloride
DPBS	Dulbecco's phosphate-buffered saline
DSPE-mPEG2k	1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[methoxy(polyethylene glycol)-2000]
EPR effect	Enhanced permeation and retention effect
FCS	Fluorescence correlation spectroscopy
FCCS	Fluorescence cross-correlation spectroscopy
hbPG	Hyperbranched polyglycerol
GOI	Gene of interest
HBV	Hepatitis B virus
HBVpreS	Large HBV envelope protein
LDLR	Low density lipoprotein receptor

LNP	Lipid nanoparticle
MIC	Minimum inhibitory concentration
MPS	Mononuclear phagocytic system
mRNA	Messenger RNA
NTCP	Sodium-taurocholate cotransporting polypeptide
ORI	Origin of replication
PDI	Polydispersity index
PEG	Polyethylene glycol
polyA	Polyadenylation
pSar	Polysarcosine
qPCR	Quantitative polymerase chain reaction
RES	Reticuloendothelial system
RISC	RNA-induced silencing complex
RNAi	RNA interference
SCID	Severe-combined immunodeficiency
SCV	Salmonella containing vacuole
siRNA	Small interfering RNA

ACKNOWLEDGEMENTS

First and foremost, I would like to thank **Prof. Jörg Huwyler** for the supervision of this PhD project and for giving me the opportunity to work in this exciting field. It was a great experience to work in his team and he always had time and gave great advice throughout the whole time. I am very grateful for the support and the feedback he provided and for the great working atmosphere in his lab. Thank you for the great time I had during my PhD.

For his co-referee, for his feedback on presentations and the PhD project in general, and for the uncomplicated collaboration, I would like to thank **Prof. Alex Odermatt**. Furthermore, I would like to express my gratitude to **Prof. Paola Luciani** for being the external expert in this doctoral committee and to **Prof. Daniel Ricklin** for his chair during my PhD defense.

A big thank you goes to **Dr. Dominik Witzigmann** for his great and constant support throughout the whole time of my PhD. I thank him for introducing me to the topic of gene delivery, for great discussions and ideas and for his most valuable feedback. He always had time for me and his enthusiastic and motivating kind provided great atmosphere during worktime. I very much appreciated the time I was working with him and under his supervision and I also enjoyed the occasional after-work beers.

I would like to thank **Dr. Philip Grossen**, **Dr. Stefan Siegrist**, and in particular, **Dr. Sandro Sieber** for the great atmosphere during the first three years of my PhD. It was a great experience to work with you and I also enjoyed our activities away from work very much. Thank you very much Sandro for introducing me to the zebrafish animal model and for all the feedback you gave during this whole time.

Furthermore, I would like to thank all collaborators from publication. In par-

ticular, I would like to thank **Prof. Andreas Zumbühl** for giving me the opportunity to synthesize aminolipids in his lab in Fribourg and for the warm and welcoming atmosphere during my trips to Fribourg. Also, I would like to express my gratitude to **Dr. Philipp Uhl** for the possibility to visit Heidelberg and to experience *in vivo* trials and radiolabeling first hand. Furthermore, I would like to thank **Prof. Beat Thöny** and his group, and in particular, **Nicole Rimann**, for introducing me to minicircle DNA amplification and **Prof. Mark Helm**, **Dr. Matthias Voigt**, and **Lukas Gleue**, as well as **Prof. Rimma Abramovich** and **Dr. Yury Nikolaev** for the opportunity to work in the field of antibiotics research.

I would like to thank **Dr. Susanne Schenk** for all the support I received from her. Thanks to her constant support and all the work she does for the whole lab, I had the privilege to be able to focus completely on research. Her valuable inputs and her advice helped me a lot. I would also like **Dr. Tomaz Einfalt** for his valuable inputs and for reviewing parts of the thesis, and, of course, I want to thank all the members of the **Pharmaceutical Technology** group. I had a great time in this lab and the members of the team all share a great open-minded attitude. Thanks for the fruitful discussions and valuable inputs and for the great time in general.

I would like to thank all my friends in Basel and in Hochdorf for always being there and for the great time away from work. In particular, I would like to thank my flat mates **Andreas Heilmann** and **Katja Fromm** for the great time I had living together with you. I would also like to thank my carnival group **Philharmoguuger Hochdorf** for the great times during carnival and throughout the year and for the (at times) welcome distraction from work at the weekends.

Special thanks go to my parents **Josef** and **Romy Buck**. They always sup-

ported me and were always there for me when I needed it. Without their support, I would not stand where I am now. In addition, I would also like to thank my brother **Kilian Buck** for being a brother but also a great friend to me.

Finally, the greatest thanks go to my girlfriend **Ursina Stadelmann** for always being there for me and for motivating me. Thank you for your endless support and for being by my side. I am indescribably happy to have you by my side and I am happily looking forward to our future.

Curriculum Vitae

January 2021

Personal Information:

Surname:	Buck
First name:	Jonas
Address:	Hauptstrasse 1, 6280 Hochdorf
Mobile:	079 718 98 44
E-Mail:	jonas.buck131@gmail.com
Date of birth:	03.09.1988
Civil status:	Unmarried
Nationality:	CH

Education:

08/2016 – 04/2020	PhD candidate at the University of Basel in the field of Drug Targeting supervised by Prof. Jörg Huwyler
09/2012 – 07/2014	Master of Pharmaceutical Sciences at the University of Basel
09/2009 – 07/2012	Bachelor of Pharmaceutical Sciences at the University of Basel
08/2001 – 07/2007	High school, Kantonale Mittelschule Seetal
08/1995 – 07/2001	Primary school, Hochdorf

Experience:

07/2020 – Today	Head Galenic Research & Development, Vesifact AG, Baar
08/2016 – 04/2020	PhD candidate at the University of Basel in the field of Drug Targeting supervised by Prof. Jörg Huwyler

05/2016 – 07/2016	Internship at the University of Basel in the field of Drug Targeting supervised by Prof. Jörg Huwyler
07/2014 – 12/2015	Principal Associate in the field of Formulation Research & Development, F. Hoffmann-La Roche AG, Basel
12/2013 – 06/2014	Master thesis project in the field of Formulation Research & Development, F. Hoffmann-La Roche AG, Basel
10/2013 – 11/2013	Internship in the field of Formulation Research & Development, F. Hoffmann-La Roche AG, Basel
2011 – 2013 (During semester break)	Employee in the field of plastic manufacturing, Plastika Balumag AG, Hochdorf
2009 – 2010 (During semester break)	Craftsman, Eiholzer AG, Baldegg
03/2008 – 01/2009	Military service, Swiss Armed Forces
08/2007 – 02/2008	Employee in the field of metalworking, Seven-Air Gebr. Meyer AG, Hitzkirch

Languages:

German	Native speaker
English	Fluent
French	High school knowledge

Personal Interests:

Traveling, trombone playing, member of a carnival music group, playing cards (Jass)

Conferences:

Poster presentation:	Swiss Pharma Science Day in Bern, August 2019
	Annual Research Meeting Pharmazentrum Uni Basel, Februar 2019
	Swiss Pharma Science Day in Bern, August 2018
	PhD Retreat Bio/Pharm Uni Basel in Engelberg, Juni 2018
	Annual Research Meeting Pharmazentrum Uni Basel, Februar 2018
	ILS Liposome Advances and Liposome Research Days Combined Conference in Athen, September 2017

Swiss Pharma Science Day in Bern, August 2017

PhD Retreat Bio/Pharm Uni Basel in Montreux,
Juni 2017

6. EuPFI-Konferenz (European Paediatric
Formulation Initiative) in Athen, September
2014

Awards:

Poster Award Special Prize	12. Swiss Pharma Science Day in Bern, 28. August 2019 for the poster: "Development of a Salmonella Infection Model in Zebrafish Embryos"
Best Poster Award	6. EuPFI-Konferenz (European Paediatric Formulation Initiative) in Athens, 17. – 18. September 2014 for the poster: "Development And Characterization of Dispersible Tablets Employing Novel Characterization Methods"
